ACKNOWLEDGMENTS

We would like to thank Frank Tesar and Nancy Thurber for their skillful orchestration of field efforts and laboratory activities, and John C. Ayers for his guidance and support throughout the project.

We are grateful to all the people who spent long hours in the screenhouse and on the lake collecting larval fish: Pat Berry, John Dorr III, Don Einhouse, Mike Enk, Loren Flath, Ron Gamble, Greg Godun, Tim Miller, Laura Morris, Richard Palacios, Michael Perrone, Paul Rago, Frank Tesar, and Nancy Thurber. In addition to their contributions to the field work, the following people deserve kudos for their expertise and patience in sorting and identifying fish larvae and eggs: Sheryl Corey, Scott DeBoe, Jim Greiner, Philip Hirt, Janet Huhn, Jeff Laufle, Gerard Lillie, Rick Moyer, Jodie Schlott, David Smith, and Jim Wojcik.

Tim Henry, Bill Yocum, and Mark Weishan designed and maintained our entrainment pumps. Captain Edward Dunster, first mates Earl Wilson and Glen Tompkins, and marine superintendent Cliff Tetzloff competently operated and maintained the R/V Mysis throughout the course of our study. Tom Kreisel, John Barnes, and Eric Mallen piloted the R/V D. C. Cook and acted as liaisons with Cook Plant personnel and coordinators of on-site operations.

Thanks to Judy Farris for valuable administrative assistance, and Dorothy Mohler for data entry. Greg Godun, Richard Palacios, and Laura Morris contributed data management and computer programming skills. Scott DeBoe performed many of the statistical analyses. Michael Perrone and Paul Rago helped with calculation methods, data processing, and review of the alewife survival section. Peter Gable drafted figures for this report and Janet Huhn and Mary Sweeney assisted with text-processing.

The project was funded by a grant to John Ayers from the Indiana and Michigan Power Company, a subsidiary of American Electric Power Service Corporation.

INTRODUCTION

PURPOSE OF THE STUDY

Mortality induced by entrainment of fish eggs and larvae and impingement of juvenile and adult fishes may be the most important biological influence power-generating plants exert on nearshore fish populations. These impacts clearly overshadow thermal discharge effects. Entrainment could significantly affect local Lake Michigan fishes by reducing the reproductive potential of important forage or gamefish populations. Because of this potential impact of the Donald C. Cook Nuclear Power Plant, we have intensively documented species, sizes, and numbers of fish larvae and eggs that were entrained at the plant from 1975 to 1982. In this report we will attempt to identify, interpret, and predict the effects of fish larva and egg entrainment on southeastern Lake Michigan's nearshore fish populations. Data in this report will cover the period 1980-1982. See Bimber et al. (1984) for 1973-1979 data summaries.

Schubel and Marcy (1978) defined two forms of entrainment - intake or pump entrainment and plume entrainment. Intake entrainment is the capture and inclusion of organisms, in our case fish eggs and larvae, into water used for condenser cooling. Plume entrainment is the attraction or mixing of adults and larvae from lake water near the discharge into the thermal plume. We did not sample plume-entrained eggs or larvae because of difficulties encountered in adequately and safely collecting organisms from this area. Effects of plume entrainment on adults are discussed in the adult and juvenile fish report prepared by the Great Lakes Research Division as part of the Cook Plant study (Tesar et al. 1985, Jude and Tesar 1985). In this report, entrainment, unless otherwise noted, will refer specifically to intake entrainment.

To more clearly define the effects of entrainment on southeastern Lake Michigan's fish community, we must (in addition to documenting species, sizes, and numbers entrained) relate those losses to the distribution, abundance, and life cycles of fishes near the Cook Plant and assess the associated effects on individual fish populations and community structure. The ultimate effect of entrainment losses will be dictated by the system's "resiliency", i.e., environmental stability, productivity, population compensation, and the ecological and economic importance of individual species. To attain these goals, we conducted field studies to identify the species, sizes, numbers, spatial distribution, and seasonal occurrence of adult fish, fish larvae, and eggs near the Cook Plant.

Most fishes in our study areas have similar seasonal movement patterns, usually related to spawning activity. They move inshore for spawning in early spring or summer where they remain until moving into deeper water in fall. Salmon, trout, and coregonines differ from this basic pattern and are usually present in spring, fall, and during upwellings. Entrainment losses generally peak during and shortly following spawning and are sporadic thereafter. Mortality of eggs and larvae during entrainment is the result of a combination of mechanical, thermal, and chemical stresses.

Field studies were used to identify the species, sizes, numbers, spatial distribution, and season of occurrence of fish larvae and eggs near the Cook Plant. We compared field and entrainment results to determine the amount of agreement between them, elucidate the biological causes for disagreement, and evaluate the adequacy of the two sampling programs. Lastly, we suggested how the location, design, and seasonal schedule of operation of water intakes on southeastern Lake Michigan could affect the rate of entrainment of eggs and larvae of inshore fishes. Our findings and interpretations are the subject of this report.

STUDY AREA

The Donald C. Cook Nuclear Power Plant occupies part of a 263-ha site on the southeast shore of Lake Michigan that includes approximately 1,326 m of dunes shoreline. The plant is located about 3 km northeast of Bridgman, Michigan, in Lake Township, Berrien County (Fig. 1).

With both reactors on line, the Cook Plant has a generating capacity of 2,200 megawatts of electricity. The plant utilizes a once-through cooling system capable of a maximum service water flow rate of 104 m³/s to dissipate an estimated heat rejection rate of 3.9 X 10° Kg-calorie/h (AEC 1973). Condenser design modifications account for differential flow rates for Unit 1 (45 m³/s) and Unit 2 (59 m³/s). Temperature increases (Δ T) over ambient lake water temperatures are 12.1 C° (Unit 1) and 9.3 C° (Unit 2) at maximum generating capacity (AEC 1973). Decreased flow rates and slightly increased Δ Ts occur in winter when heated water is pumped back through the intake structures via one of the three intake pipes to reduce ice formation.

Water for both condenser units is drawn from Lake Michigan through three intake structures 686 m offshore in 7.3 m of water (mean lake level - 176.5 m above sea level). Intake structures rest on a concrete and riprap base structure approximately 2 m

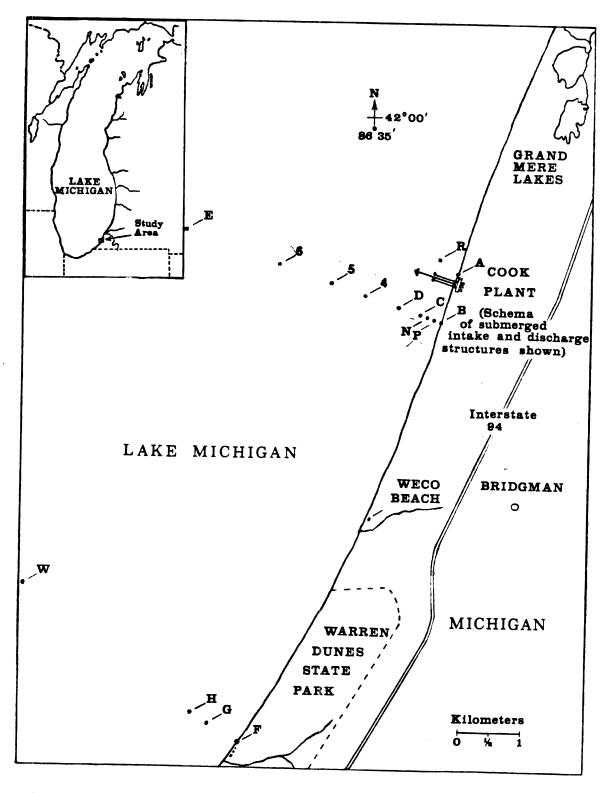

Figure 1. Map of southeastern Lake Michigan, showing locations of the D.C. Cook Plant and our field fish larvae sampling stations.

above lake bottom. Intake openings, protected by a series of steel guard racks, are an additional 2.5 m above the base. Therefore, intake water is drawn from the 2- to 5-m strata of the water column. Three intake pipes with diameters of 4.9 m are buried in the lake bottom and covered by at least 0.6 m of sand (AEC 1973). Estimated water velocity at the intake grills (20 X 20-cm openings) is approximately 0.4 m/s during normal conditions and 0.6 m/s during winter de-icing operations. In the intake pipes, water velocity increases to 1.8 m/s during normal conditions (AEC 1973). Cooling water travels through the intake pipes to a common screenhouse where the seven circulating water pumps are located (Figs. 2 and 3).

Water then passes through vertical trash racks (6-7-cm openings, 0.3 m/s water velocity) and vertical traveling screens (0.95-cm square openings, 0.6-m/s water velocity) to circulating water pumps and condensers. Heated water is discharged via two buried pipes (4.9-m diameter). Discharge structures are 91 m apart and 366 m offshore in 5.5 m of water. Water is discharged at a rapid rate (6,202 m³/min) through slot-jet diffusers which rapidly mix heated and ambient water. The effluent plume has an estimated area during two-unit operation of 230 ha within the 1.7 C° Δ T (3 F°) isotherm (AEC 1973). A more detailed discussion of intake and discharge structures may be found in Jude et al. (1979b), AEC (1973), and IMPC (1977, 1979). Cooling water passage time from intake at the 7.3-m contour in Lake Michigan to discharge at the lake's 5.5-m contour is approximately 10 min; duration of condenser passage is about 6 s (AEC 1973).

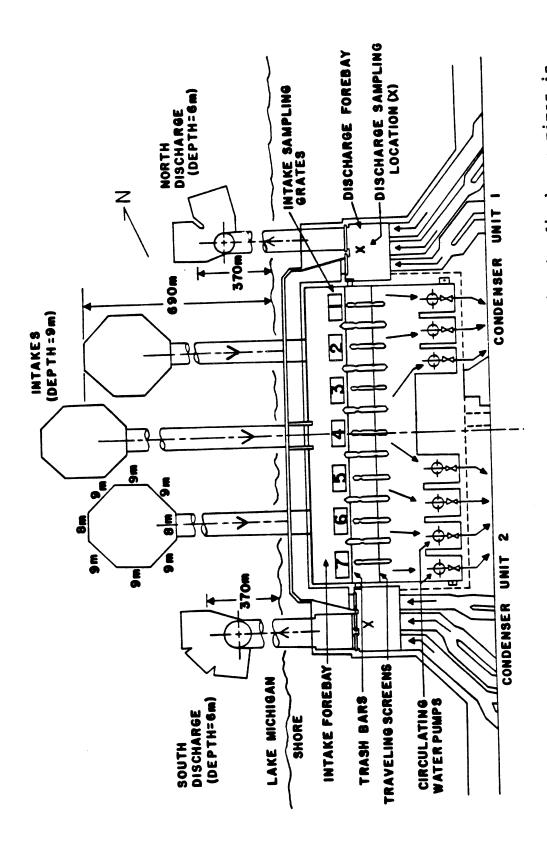

Figure 3. Diagram of the screenhouse and the plant's intake-discharge pipes in Lake Michigan. Also shown are the traveling screens, circulating water pumps and forebay grates where entrainment sampling was conducted.

METHODS

FIELD LARVAE

Sampling

Fish larvae were collected with a conical, 0.5-m diameter, nylon plankton net of no. 2 $(363-\mu\text{m})$ mesh. A Rigosha flowmeter attached to the center opening of the net measured volume of water sampled. When flowmeters failed to function, we substituted the average of flowmeter values from the remaining tows at the same station or from stations of comparable depth. Flowmeter readings were converted to volume filtered by use of the calibration method in Jude et al. (1979b). One revolution was equal to approximately 15 liters of water filtered.

Duplicate surface tow samples were collected at beach seining stations A (north Cook), B (south Cook), and F (Warren Dunes). A net was towed by hand, just below the water surface, against the current for a distance of about 61 m, once during the day and once at night. Beach tows were performed once a month, April through November.

We performed horizontal, 5-min tows from the R/V Mysis at speeds of 3-6 km/h at discrete depths parallel to shore along three transects in Lake Michigan. The transects were at Warren Dunes, including stations F (1 m, i.e., beach), G (6 m), H (9 m), and W (21 m); south Cook, with stations B (1 m), C (6 m), D (9 m), and E (21 m); and north Cook, with stations A (1 m) and R (6 m) (Fig. 1). Open water tows were performed both day and night, once per month, April through September (1980-1981) and April through August (1982). Stations E and W (21 m) were not sampled after May 1982. For 6-m stations a tow was done at 0.5, 2, 4, and 5.5 m; for 9-m stations depths were 0.5, 2.5, 4.5, 6.5, and 8.5 m; and for 21-m stations tows were done at 0.5, 7.5, 13.5, and 20 m.

The procedure for deepwater tows was as follows:

- Plankton net with attached Mason jar and depressor lowered to desired depth on end of cable.
- 2) Plankton net towed horizontally for 5 min starting at the desired depth, which was obtained by measuring cable angle and trigonometrically calculating the length of cable to be released to reach desired depth.
- Plankton net hauled to surface and washed with a water hose.

4) Contents rinsed into the Mason jar, preserved with 40 ml of buffered formaldehyde, labelled, and sealed.

Total numbers of larvae and eggs captured in all subsurface tows were adjusted to compensate for upper strata contamination. For details of calculation see Jude et al. (1979b). Numbers of eggs and larvae were converted to densities, i.e., number/1,000 m 3 , for all analyses. About 35 m 3 of water were filtered during most tows.

Statistical_Analyses

ANOVA was applied to fish egg density and larval fish density data (no/1,000 m³) of four species: alewife, yellow perch, spottail shiner, and rainbow smelt. All ANOVA designs were Model I, full factorial, balanced designs calculated with the statistical package BMD8V (unpublished ms. Statistical Research Laboratory, Univ. Mich., Ann Arbor, Mich. 48109). To approach the assumptions of the model more closely, densities were transformed using log (density + 1). Data from two zones, beach and open water, were analyzed separately. In the beach zone, factors used in ANOVA included Year (1973-1982), Month (June-August), Station (A, north Cook; B, south Cook; and F, Warren Dunes), and Diel Period (day and night) for alewife and fish eggs. Factors used in ANOVA applied to spottail shiner data were Year (1973-1982), Month (June-August), and Station (A, B, F). Due to excessive daytime net avoidance exhibited by spottail shiner larvae, only nighttime samples were included in the analyses. Larval rainbow smelt were abundant enough during May of some years to apply ANOVA tests. Factors utilized in analyses of larval rainbow smelt densities included Year (1974-1975, 1980-1982), Station (A, B, F), and Diel Period. Yellow perch larvae were too scarce in the beach zone for examination with ANOVA.

In the open water zone, factors used in the analysis of alewife larvae densities included Year (1973-1982), Month (June-August), Area (Cook and Warren Dunes), Depth (6- and 9-m contours), and Diel Period. Year (1974-1975, 1979-1982), Area, and Depth were the factors used in ANOVA applied to spottail shiner density data. Only nighttime samples taken in July from the open water zone contained enough spottail shiner larvae to be examined using ANOVA. Factors used in ANOVA applied to larval rainbow smelt density data included Year (1974-1975, 1980-1982), Area, Depth, and Diel Period. Only data from the month of May were utilized in rainbow smelt ANOVA. Larval yellow perch were abundant enough in the open water zone during June of some years for examination using ANOVA. Factors used for yellow perch analyses were Year (1973-1974, 1977-1982), Area, Depth, and Diel

Period. Factors used for fish eggs in the open water zone were Year (1974-1982), Month (June-July), Area, and Depth, but only night data were included.

Because preliminary tests showed no significant trend in larval fish densities among depth strata (surface to near bottom) for a given sampling site and time, samples from different depth strata from the same site and time (day or night) were used as replicates in the ANOVAs of open water stations. Since larval fish samples were taken at 2-m intervals in open water, stations at 6 m, (C, south Cook, and G, Warren Dunes) had one less replicate than 9-m stations (D, south Cook, and H, Warren Dunes). To balance the design, the mean of densities from the four strata at 6-m stations replaced the missing 8-m value. The unweighted means method for balancing designs (Fox, D. J., unpublished ms, Statistical Res. Lab., Univ. Mich., Ann Arbor, MI 48109) was then applied to the open water results. Treatment sums of squares were multiplied by the ratio of harmonic mean cell size to maximum cell size to adjust for substitutions, and the number of missing values was subtracted from degrees of freedom of the error term to adjust mean square error.

ENTRAINMENT

Sampling

Species and numbers of larvae and eggs entrained at the Cook Plant have been monitored by standardized sampling since 1974. However, sampling in 1974 was limited because of the sporadic testing of condenser cooling systems. These data are presented in detail in Jude (1976) and Jude et al.(1979b). Bimber et al. (1984) analyzed data collected from 1973 to 1979. This report will emphasize analysis of data collected during operational years 1980 to 1982, and will include an overview of field larvae collections from 1973 to 1982 and entrainment losses at the Cook Plant from 1975 to 1982.

An entrainment sampling unit included a Hale (type 30LC-1750) diaphragm pump (maximum capacity, 300 liters per minute; mean capacity, 208 liters per minute) with a 7.6-cm diameter steel pipe extending into the intake forebay to a depth of 5 m (Fig. 4). The 5-m depth (maximum depth in the forebay is 9 m) was chosen because of results of our vertical and horizontal stratification testing in 1975 (Jude 1976). Water was pumped through a 0.5-m diameter, no. 2 Nitex nylon, $363-\mu$ m mesh plankton net suspended in a 208-liter drum. A flowmeter installed in the drum's effluent pipe measured the volume of water filtered. Standard entrainment sampling units (three) were located at grates 2 and 3 and one at the Unit 1 discharge (Fig. 4). Sampling was performed at the Unit 2 discharge on those occasions when

Unit 1 was not operating. Seven grates span the length of the screenhouse forebay floor. Most sampling in 1980-1982 was done at grates 2 and 3. Unit 1 circulation pumps draw most of their water under grates 1, 2, and 3 (Fig. 3).

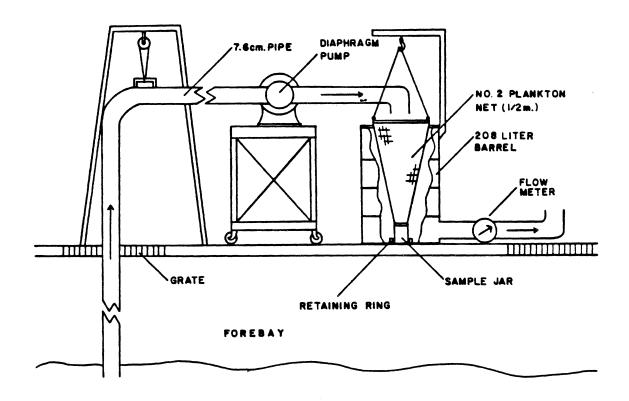

Figure 4. Schematic diagram of an entrainment sampling unit, showing the forebay, sampling pipes, diaphragm pump, plankton net, and flowmeter in the discharge pipe.

Standard series entrainment samples were collected twice per month, except for June, July, and August when sampling was done once per week to coincide with peak abundance of fish eggs and larvae. Sampling was conducted twice per week during June-August 1981 and June-July 1982. Samples were collected over a 24-h period. Each 24-h period was divided into four diel sampling divisions which varied from 4 to 8 h, depending on division and day length. The four divisions were sunrise-noon, noon-sunset, sunset-midnight, and midnight-sunrise. Sixteen samples, four replicates (three intake, one discharge) per division, were collected for each 24-h period.

Densities of larvae and eggs represent a conversion of number per volume sampled (the amount of water pumped through the plankton net) to number per standardized volume (1,000 m³). These standardized mean densities of larvae and eggs were expanded to the volume of water circulated by the plant during the time represented by that diel period. The total number of fish and eggs entrained over 24 h was computed by totaling estimates from each of the four diel sample divisions during a sample period. Each of these four estimates was derived by multiplying the mean density (n = four) times the total volume of water pumped through the plant during the time represented by that particular division. For yearly estimates, non-overlapping, contiguous time intervals (usually 1-2 wk) were established such that the sampling date was the approximate midpoint of the interval. Estimated entrainment during a sampling period was assumed to be representative of fish larvae and egg abundance per unit volume of circulating water during the 1-2-wk sample interval. The estimated number of fish larvae and eggs entrained was expanded accordingly. These data were totaled for each month and then yearly estimates computed.

Analysis of entrainment data for alewife larvae, total larvae, and fish eggs (log (density + 1) transformed data) was carried out using the Analysis of Variance subprogram of the Statistical Package of the Social Sciences (SPSS) (Nie et al. 1975). A three-factor, fixed-effects, non-additive model was considered most appropriate, with the three factors being: Year, Grate, and Diel Period. To obtain the most balanced model (least amount of missing data) only data from years 1976 through 1982 were examined and data from both discharge grates were combined (since they were not sampled simultaneously). Thus the analysis was across 7 years, four grates, four diel periods, and their associated interactions. Sample size was 1,699. Similar results were obtained for each ANOVA in that the only factors which exhibited attained significance levels less than 0.01 were Year and Diel Period.

Sample Types

The Cook Plant entrainment sampling regime has been modified several times during the course of this study. Four classes of samples describe the use or type of sample collected: standard, supplemental, processed but not used, and not processed (discarded or lost).

Standard series samples were those that could be compared with others in terms of location, duration, and frequency of sampling. Standard samples were collected from grates 2 and 3, and from either the Unit 1 or Unit 2 discharge during any of four diel periods (midnight to sunrise, sunrise to noon, noon to

sunset, or sunset to midnight); depth was 5 m. Volume of water filtered for each sample must have been consistent with volumes of other standard samples collected during the same diel period. A complete standard series sampling set resulted in the collection of 16 samples, 4 samples (3 intake, 1 discharge) from each of the four diel periods.

Supplemental samples were those taken to examine the vertical and horizontal stratification of fish larvae and eggs in the forebay; samples extending across diel periods (i.e., samples taken all night, all day, noon to midnight, midnight to noon, or for 24 h); samples for which inadequate data concerning location of sampling were recorded; and samples taken from grates other than 2, 3, or Unit 1 discharge. Data from supplemental samples were used to support conclusions concerning heterogeneity in the distribution of larvae and eggs in the forebay and to increase the entrainment data base for improving estimates of entrainment losses.

Entrainment samples which were not comparable to others collected during the same time period were removed from the analyses. These samples included: 1) samples in which volumes of water filtered were substantially reduced (less than 75 liters per minute), 2) reduced sampling duration (usually as a result of pump or power failure), or 3) any other problem samples. Samples which were lost, broken, or inadequately preserved comprised this final category. These samples were noted but not included in the entrainment data base.

Entrainment Sampling Adequacy

Over 4,100 entrainment samples, containing nearly 21,400 fish larvae and 603,000 eggs, were processed during 1975-1982 (Tables 1, 2). Standard series samples (see Sample Types) accounted for between 53% (1975) and 98% (1981) of the total number of samples collected in any year. The actual number of larval fish collected in a given year has ranged from 528 (1978) to 4,267 (1982) (Table 2) with a mean of 2,667 larvae/year. Alewife have accounted for over 3/4 of all fish larvae collected in entrainment samples during the 8-yr study period. The number of eggs found in entrainment samples has ranged from 22,418 (1979) to 153,416 (1982) (Table 2) with a mean of 75,315 eggs/year.

As a result of the large quantity of water used for condenser cooling, current entrainment sampling techniques allow inspection of only a very small fraction of the total intake water volume (Table 3). During 1975-1982 a mean of 0.00165% of the total annual flow was sampled. Sampling effort was increased during June, July, and August in each year (see Sampling) and the

1982	1982 2,749,400	34.7	0.00126	586,900	18.4	0.00314

percentage of cooling water sampled increased to 0.00294% for the 3-mo period. During one-unit operation (1975-1977) June-August sample volumes were 0.00409% of the total; during 1978-1982, when two units were on-line, sample volumes dropped to 0.00224% of the total June-August flow.

Sampling During 1980-1982--

Entrainment sampling during the final years of our study was very consistent. Standard series sampling was conducted at grates 2, 3S, and 3N and the Unit 1 or Unit 2 discharge at a depth of 5 m (Tables 4-6). When Unit 1 was not operating, Unit 2 discharge samples were substituted for standard series sampling. Samples were collected twice per month, except in June-August 1980 and August 1982 when sampling occurred weekly and in June-August 1981 and June-July 1982 when samples were taken twice each week. Supplemental samples (miscellar ous long duration or non-standard-series location entrainment samples) were collected during June-July 1980, August 1981, and July-September 1982. For a description of sampling during 1974-1979 see Jude et al. (1979b) and Bimber et al. (1984).

Forebay Heterogeneity Studies--

Stratification of organisms within the water column is a potential source of error in any entrainment sampling program. The subject is often ignored, or statements about the highly mixed nature of the cooling water are used to justify arbitrarily chosen sampling locations.

During 1974 and 1975 studies were conducted in the forebay at the D. C. Cook Plant to determine whether fish larvae and eggs were clumped horizontally or vertically in the water column. Sampling was performed at depths of 2, 5, and 8 m and ANOVA examination showed no significant difference for total fish larvae, alewife larvae, or fish egg densities with depth (Jude 1976, Jude et al. 1979b, Bimber et al. 1984). Although the differences were not statistically significant, the 5-m sample means were greatest for all three categories and thus 5 m was selected as the depth at which standard series sampling would be carried out. The horizontal distribution study likewise revealed no statistically significant differences among sampling locations (i.e., different grates) in the forebay (Jude 1976, Jude et al. 1979b, Bimber et al. 1984).

As in previous years (see Bimber et al. 1984), data collected from 1980 to 1982 were examined for evidence of fish larvae and egg stratification in the forebay. ANOVA was used to compare differences in densities among the various standard

series sampling locations. No significant differences in densities of total larvae or alewife larvae occurred among samples collected at grates 2, 3N, 3S, and Unit 1 or 2 discharge during 1980-1982 (Table 7) or during 1976-1982 (Tables 8,9).

There was no significant difference in egg densities among sampling locations for all years combined. The ANOVA with the most balanced design included 1976-1982 with egg densities from Units 1 and 2 discharges pooled (Table 10). When Units 1 and 2 discharges were treated separately in the ANOVA, there were significant differences in egg densities among grates in 1981 and and 1982 (p <0.001). Mean densities for June-August 1982 were 13 eggs/1,000 m³ at Unit 1, and 2 eggs/1,000 m³ at Ūnit 2. However, when 1982 data for Units 1 and 2 discharges were combined, their mean (9 eggs/1,000 m³) was similar to those of the other grates (10-11 eggs/1,000 m³) so that no difference was detectable (Table During 1979 and 1981, mean egg densities at Unit 2 discharge were much higher than at Unit 1 discharge, in contrast with 1982. These results caused a significant YEAR x GRATE factor interaction for the years 1978-1982 (p <0.001). The differences between discharges were probably due to a combination of discharge design, flow rates, and demersal nature of the eggs, which dictated whether eggs were mixed throughout forebay waters, and hence, susceptibility to our pumps. An unanswered question is whether adult fish impinged on the traveling screens released eggs which could be collected in discharge samples. However, there is no reason to believe that this would occur with greater frequency at one discharge than the other. Analysis of the data showed egg densities were not significantly higher at the discharges than the intakes, thus egg release by impinged fish is probably small in comparison to total eggs entrained.

Field-Entrainment Comparisons

Field and entrainment catches were compared for abundance and size of alewife larvae and abundance of fish eggs in an effort to determine if larvae and eggs were entrained in proportion to their abundance in the lake. Each set of monthly field samples (June-August, day and night separately) was paired with the set of entrainment samples taken on the nearest date, during the same diel period. Relative abundance was determined by comparing densities (no./1,000 m³) of larval alewife in each pair of samples. The density computed for each diel period of entrainment sampling was the mean of eight replicates (day = dawn to noon and noon to dusk samples combined; night = dusk to midnight and midnight to dawn). Entrainment densities were compared to densities from field stations in close proximity to the intakes (i.e., 9-m station D and 6-m stations C and R). Field densities for a given diel period therefore represented a

mean of 13 samples: (mean of C+R (N=8) + mean of D (N=5))/2. A weighted average was used to equalize the contribution of 6- and 9-m stations.

Because alewife eggs can hatch in 3 days at the 20-23 °C temperatures typical of Lake Michigan in summer (Auer 1982) and because intermittent upwellings and movement of water masses can transport larvae to and from the nearshore zone (Heufelder et al. 1982), sample pairs taken more than 2 days apart were excluded from the analysis (10 cases). Field densities were greater than entrainment densities in 32 of the remaining 38 cases (84% of the time).

Field and entrainment samples were paired the same way for length comparisons as for abundance comparisons. Sample sets taken more than 2 days apart were again excluded as were samples containing fewer than five larvae (three additional cases).

ESTIMATION OF ALEWIFE SURVIVAL

Introduction

Survival of alewife during the first growth season was estimated as follows. Because alewife spawning and hatching are continuous over 1.5 months or longer, it was impossible to identify a cohort and follow it through the season. Thus data for larvae and YOY were pooled through the season and treated as one cohort. Fish were separated by length intervals but not by sampling period.

Densities of Alewife Larvae

Densities of alewife larvae used in the analysis were obtained from both field and entrainment samples. Entrainment densities were calculated for each year by averaging the densities for each sampling period, then summing the means over all sampling periods (n usually equalled 16) to get a total mean density of larvae pooled through the season. This was done separately for size groups 2-5 mm (newly hatched), 5.5-10 mm, 10.5-15 mm, 15.5-20 mm, 20.5-25 mm, and 5.5-25 mm pooled, separately for each year. An estimate of growth rate is necessary to obtain survival rates from length-frequencies (Farris 1960, May 1974). Alewife larvae in the laboratory grow at rates of 3.5 to 4.6 mm per wk (Heinrich 1981, Kellogg 1982) and take an average of 5 wk to grow to 25 mm (Heinrich 1981). Entrainment samples were usually collected once a week, so fish larvae hatched at a given time could be sampled three or four

times during their growth from 5.5 to 25 mm. Therefore, larvae 5.5-25 mm were separated into size groups so that total density over the season would not include the same age group more than once. Samples were taken twice weekly during 1981 and 1982, so 1981-1982 total entrainment densities were halved to make them comparable with all other years. All diel periods were combined.

Only field larvae samples from stations 6 and 9 m in depth (C, D, and R - Cook, G and H - Warren Dunes) were used in the analysis, because these were the depths for which trawl data were available. Densities were averaged over all depth strata and stations, then summed over the months alewife larvae were collected (usually June through August, sometimes including September). Samples from the diel period showing greatest abundance of alewives were used, usually night. Some day sample densities were higher than for night, and were used during 1977, 1978, 1979, and 1980. Densities of newly hatched larvae were calculated separately from densities of larvae >5 mm, but larvae >5 mm were not subdivided further because field sampling was conducted monthly, and this was a long enough time for most to grow from 5 to 20 mm. So few larvae 20-25 mm were collected that their densities did not significantly affect results. larvae data from 1973 were not included because different strata were sampled that year and would bias results.

Densities of YOY Alewives

Size and shape of the trawl mouth were estimated from published studies of trawls in motion, along with measurements of our trawl on land. Amos et al. (1981) used a towing tank to test an otter trawl which was constructed like ours (only somewhat larger). Lengths of headrope, footrope, vertical line, and bridle were compared between their tested trawl and ours (Table 11). Proportions of these measurements and Amos et al.'s measurements of trawl mouth size during towing were used to estimate likely size and shape of our trawl mouth opening. estimates were compared with results obtained by Hatch et al. (1981), who found a somewhat larger vertical opening on a trawl similar to ours; therefore our estimate of vertical opening was adjusted upwards in proportion to the headrope length and vertical opening of Hatch et al.'s trawl. Amos et al.'s figures were used for shape and horizontal opening of the trawl. was obtained by plotting the dimensions on graph paper.

Distance covered during each trawl was calculated using the average speed during trawling (4,167 m/h) and elapsed time (10 min). Volume of water filtered by the trawl was obtained by multiplying distance by trawl area (2.45 m^2) . An estimated $1,701.5 \text{ m}^3$ of water was filtered during each trawl haul. Numbers of YOY in day trawls were averaged over trawl stations of the

^{*}Mean of headrope and footrope spread.

same depth, three 6-m stations and two 9-m stations. These numbers were divided by 1.7015 to obtain mean number of YOY/1,000 m³. Densities were calculated separately for each 10-mm length interval, and were summed over months in which YOY were present at trawl depths and weather permitted sampling, usually September, October, and November. Since alewife YOY are believed to concentrate near bottom during the day, densities were multiplied by the height of the trawl divided by the depth of the water column (6 or 9 m), then summed over the two bottom depths. This adjustment made trawl data comparable to field larvae data, which represented the whole water column.

Survival rates, i.e., the ratios of YOY densities to larvae densities, were calculated separately for each year using field and entrainment data for each length interval of larvae, and the density of the most abundant length interval of YOY. The peak length interval was felt to be the truest representation of YOY density, representing the time when most YOY were actually at trawl depths rather than inshore (late summer, smaller fish) or offshore (late fall and winter, larger fish). Densities for each length interval of larvae, and peak-length YOY densities, were also averaged over all years, then used to calculate survival rates for all years combined.

Daily mortality rates were calculated from field and entrainment data using the equations:

$$z = -(\ln N_{t+1} - \ln N_t)$$

$$n_+ = Z/D$$

$$M_{t} = 1 - e^{(-n_{t})}$$

where Z = instantaneous mortality rate from time t to t+1

 N_{+} = density of alewife at time t

 n_{+} = instantaneous daily mortality rate

D = number of days from time t to t+1

 M_{+} = daily mortality rate from time t to t+1

These mortality rates were calculated using mean densities over all years for the various length intervals available. Dates used were derived in two ways: (design I) mean dates of peak catch in each length interval, and (design II) dates for intermediate length intervals calculated from peak dates of yolk-sac larvae catch, and growth rates obtained in the laboratory by Heinrich (1981). Thus if peak catch of yolk-sac (2-5 mm) larvae was 7 July, Heinrich's growth rates indicate larvae should reach successive 5-mm length intervals of 5.5-10, 10.5-15, 15.5-20, and 20.5-25 mm in 7, 16, 23, and 30 days after 7 July, respectively. However, actual time of peak YOY catch was used for the date terminating the analysis, because Heinrich's data do not go beyond 50 days. Thus designs I and II are the same for calculating daily mortality over the entire span, yolk-sac larvae to YOY. Design II calculations involving the 5.5-25 mm interval used 11 days from 2-5 to 5.5-25 mm as the midpoint of growth from 5 to 10 and 10 to 15 mm, which were the intervals above 2-5 mm containing the most larvae.

LABORATORY PROCEDURES

All entrainment and field samples of fish larvae and eggs were preserved with a 10% formaldehyde solution immediately after collection and then transported to the Great Lakes Research

Division's fishery laboratory for analysis. For our purposes, fish larvae were defined as any fish 25.4 mm or less in total length (TL). In the laboratory, larvae were sorted, identified, counted, and measured. Larvae were identified to species, when possible, otherwise to the lowest taxonomic group (see Table 12). Alewife, spottail shiner, and rainbow smelt were measured to the nearest 0.5 mm TL, while all others were measured to the nearest 0.1 mm TL. Eggs were also counted but not identified to species. When large quantities were found, egg numbers were estimated via a volumetric subsampling method (see Jude et al. 1975). All larvae and a subsample of eggs from each entrainment sample were then catalogued and saved for future reference. Data were recorded directly on standard coding forms, keypunched, and transferred to computer tapes for analysis.

Larval fish identification was based on knowledge of species abundance and spawning times in southeastern Lake Michigan, comparison of specimens with those in the Great Lakes Regional Fish Larvae Collection (Dorr and Jude 1981), and reference to taxonomic works (Auer 1982, Dorr et al. 1976, Hogue et al. 1976, Lippson and Moran 1974, Nelson and Cole 1975, and Jude et al. 1979b). Some fish larvae identifications may be reevaluated and reassignments made, but these taxonomic changes will not affect total entrainment estimates in any year.

RESULTS AND DISCUSSION

OVERVIEW

Summary: Entrainment and Field Larvae Collections

Nearly 750 million fish larvae and 23 billion eggs were entrained at the D. C. Cook Plant during 1975-1982. Estimated annual losses ranged from 33.5 million larvae in 1977 to 167 million larvae in 1982 (Table 13). Differences in the volume of cooling water pumped through the plant each year (Table 14) were responsible, in large part, for the fluctuations in estimated losses. Variations in annual losses are generally caused by a combination of biological and non-biological factors, i.e., fluctuations in year-class strength and differences in plant operation.

Thirteen species of fish larvae were found in entrainment samples during our 8-yr study: alewife, burbot, common carp, deepwater sculpin, johnny darter, mottled sculpin, ninespine stickleback, quillback, rainbow smelt, slimy sculpin, spottail shiner, trout-perch, and yellow perch. In addition, there were four groups that could not be identified to species: coregonines (Coregonus spp.), darters (Etheostoma spp.), minnows (Cyprinidae), and sculpins (Cottus spp.). Approximately 8% of all fish larvae collected during entrainment sampling were damaged beyond recognition and <0.1% could not be identified at our current level of taxonomic sophistication (Table 1, Table 13).

Alewives were by far the most abundant species, accounting for between 54 and 92% of the total number of larvae entrained in every year (Figure 5) and 74% of the overall 8-yr entrainment loss. Spottail shiners represented 9% of the 1975-1982 entrainment loss, rainbow smelt represented 5%, and yellow perch 2%. Remaining taxa each accounted for <1% of the total 8-yr loss (Table 13).

Entrainment of fish larvae generally began for the year in April, peaked in June or July (when alewife spawning and hatching peaked), and terminated in October or November as larvae and young-of-the-year migrated to deeper offshore zones. Entrainment rates were strongly influenced by diel period. Use of ANOVA showed that significantly more fish eggs and larvae were entrained at night (dusk-midnight and midnight-dawn sampling periods) than during the day (dawn-noon and noon-dusk) (Tables 8-10).

Table 13. Estimates (in millions) of annual entrainment losses of fish larvae and fish eggs at the D. C. Cook Plant, southeastern Lake Michigan, 1975 to 1982. Calculations use actual reported flow rates of the circulating water system.

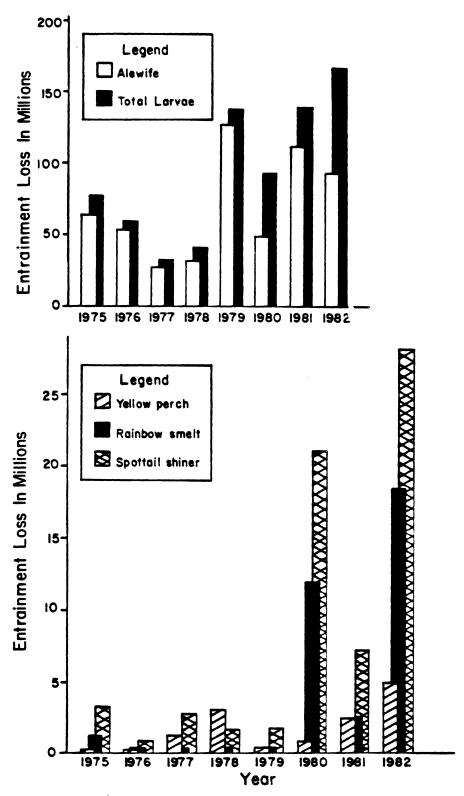

Figure 5. Entrainment losses at the D.C. Cook Plant, southeastern Lake Michigan, 1975-1982, for alewife, yellow perch, rainbow smelt, spottail shiner, total larvae, and fish eggs.

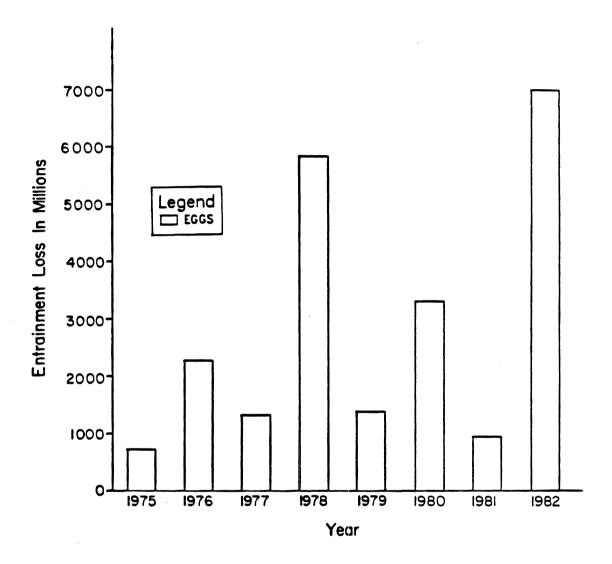

Figure 5. Continued.

Nineteen taxa of fish larvae were identified from our field samples during the 10-yr study. Alewife dominated collections in every year. Spottail shiner, yellow perch, and rainbow smelt were also present in all years, but in much smaller numbers than alewife. Burbot, common carp, johnny darter, and trout-perch larvae appeared in field samples occasionally. The remaining taxa, deepwater sculpin, emerald shiner, gizzard shad, ninespine stickleback, slimy sculpin, quillback, and unidentified members of the whitefish, herring, minnow, sculpin, and sucker families were rare; each was present in only 1 or 2 years.

Larvae first appeared in field samples in April or May and became most abundant during summer months (June-August) when spawning was heaviest. The last larvae of the season were collected in September, October, or November. Rainbow smelt, burbot, yellow perch, deepwater sculpin, and alewife were among the earliest larvae to appear during our field season; alewife, and occasionally trout-perch, were the latest.

June, July, and August samples contributed between 80 and 99% of the total number of larvae collected in each year. July was usually the month of highest mean densities of larval fish at both beach and open water stations, followed by June, and then August. During the summer, monthly mean densities were almost always higher at beach stations than at open water stations. Generally, more larval fish were caught during night sampling than during day sampling.

Plant Impact

There were few indications of Cook Plant effects on distributions of fish larvae. Statistical tests performed on densities of larval fish species which were consistently abundant enough for analysis showed few significant differences. alewife abundance did not differ significantly between Cook and Warren Dunes stations (ANOVA: p = 0.3775 for beach stations, p = 0.5758 for open water stations) over the 10 years of data collection. Densities of spottail shiner larvae in night beach station samples did not differ significantly between areas (ANOVA, p = 0.8415). Yellow perch were at depressed levels during all but the last year of our study, due to the impact of the alewife (Christie 1974; Jude et al. 1979a; Crowder 1980; Jude and Tesar 1985). Yellow perch larvae abundance followed no patterns attributable to plant operations. Yellow perch larvae were abundant in both Cook and reference areas in 1974, 1977, and 1982, but not in other years. During operational years 1977 to 1982, open water yellow perch densities were not significantly different between Cook and Warren Dunes stations (Kruskal-Wallis, p = 0.768). Additionally, no significant difference existed between preoperational and operational years for June open water

yellow perch densities (Kruskal-Wallis, p = 0.155). Beach catches of rainbow smelt larvae during 1974, 1975, and 1980-1982 did not differ significantly between Cook and Warren Dunes stations (ANOVA, p = 0.48). In the open water, densities at Cook were significantly higher than at Warren Dunes (ANOVA, p = 0.0015) when preoperational and operational years were combined (1974, 1975, and 1980-1982). This significance was due to the unusually high catches at 6- and 9-m Cook stations during May 1974. During operational years (1975 and 1980-1982), however, no significant difference between Cook and Warren Dunes open water stations (C and D vs. G and H) was observed (Kruskal-Wallis, p = 0.02). These data suggest no plant impact on larval rainbow smelt populations.

Of the less abundant species, the most striking abundance pattern was that of common carp larvae. Common carp larvae were never collected in the study area during preoperational years. During operational years, they were found mostly at Cook stations. Of the 23 samples containing common carp larvae, only 2 were collected at Warren Dunes. These data suggest that common carp spawning took place at Cook Plant stations during operational years, which we attributed to the attraction of the warm water plume and currents produced by the heated discharge of the Cook Plant. Thus common carp spawning at the Cook Plant was a clear plant effect. Common carp larvae were collected at Warren Dunes at relatively low densities (31 larvae/1,000 m³ and 83 larvae/1,000 m³). These larvae probably drifted from the Cook Plant area.

Burbot, deepwater sculpin, and ninespine stickleback larvae showed no apparent differences between Cook and reference areas. Quillback, unidentified Coregoninae, gizzard shad, emerald shiner, and others, identified only to genus or family (minnows, darters, sculpins), were collected so seldom that no difference could be ascertained. Several other species not abundant enough for statistical testing were more abundant at Cook than at the reference area. During the 10-yr study, 14 samples contained trout-perch larvae, and 10 of these were from Cook stations. More johnny darter and slimy sculpin larvae were collected at Cook than at reference stations, probably because riprap around the intake attracts these species for spawning.

DESCRIPTIONS BY SPECIES

Alewife

Entrainment--

General trends— Alewife larvae have represented the largest component of entrainment loss in every year of our study, consistently accounting for over half the total number of fish larvae entrained (Fig. 5). Annual entrainment estimates for alewife larvae ranged from 27.4 million (1977) to 125.6 million larvae (1979) and the proportion of total annual entrainment attributable to alewife has ranged from 54% (1980) to 92% (1979) (Table 13).

The apparently extraordinary susceptibility of alewives to entrainment is probably a result of several factors. Alewife is the most abundant fish species in the vicinity of the Cook Plant (Jude et al. 1979b, Tesar et al. 1985) and in Lake Michigan as a whole (Smith 1968) and it is therefore not surprising to see them so well represented in entrainment samples. Further, alewives are pelagic broadcast spawners which produce large numbers of eggs (10,000-22,407/female, Auer 1982) and larvae compared with species that provide some form of protection for embryos and larvae (e.g., sculpin).

Alewife susceptibility to entrainment is also enhanced by temporal and spatial characteristics of their spawning and hatching and distribution of their larvae. In spring or early summer, adult alewives move inshore to spawn and come within the realm of influence of the intakes. Peak hatches generally occur in June or July when demand for electricity, and therefore cooling water requirements, are also at a peak. The pelagic nature of alewife larvae increases their vulnerability to entrainment. In addition, larval alewives are among the most frail and least developed at hatching of all Great Lakes fish larvae which probably makes them less able to avoid water intakes than the larvae of many other, more robust species.

Seasonal abundance—Season of occurrence for alewife larvae generally begins in the spring as water temperatures approach 15 °C and extends through the summer months and into the fall. This period corresponds to the period of warmest water temperatures in the vicinity of the Cook Plant (Figs. 6-8, Bimber et al. 1984). Larval alewife were first entrained in April (1977), May (1975, 1976, 1978), or June (1979-1982), became most abundant in June (1975, 1981) or July (1976-1980, 1982) (Tables 15-17, Figs. 9-11) and continued to be present in entrainment samples during nearly every month until September (1975, 1977, 1980, 1981), October (1976, 1982), or November (1978, 1979).

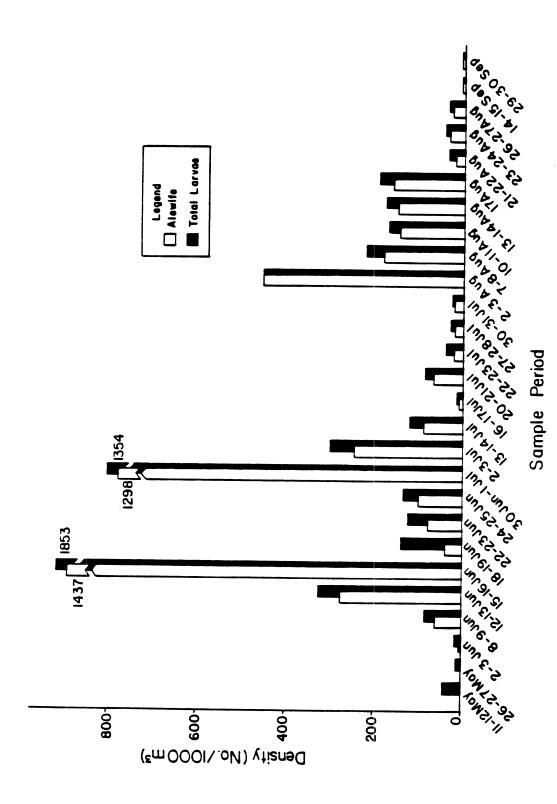

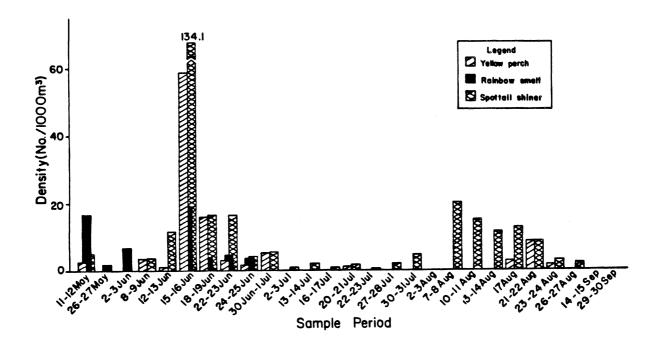

Figure 10. Density estimates of entrained fish larvae (no./l,000 m³) for alewife, spottail shiner, rainbow smelt, and yellow perch larvae, and fish eggs found in intake water used for condenser cooling at the D. C. Cook Plant, 1981.

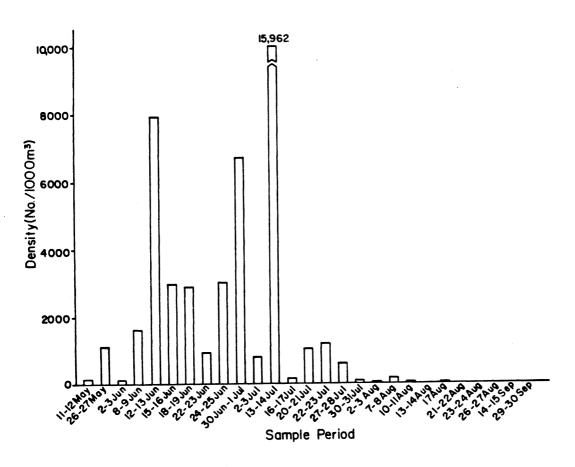

Figure 10. Continued.

The greatest mean densities in entrainment samples recorded over a 24-h sampling period (N = 16) in each year were: 1.831 larvae per 1,000 m³ (8-9 July 1975), 1,039 larvae per 1,000 m³ (20-21 July 1976), 379 larvae per 1,000 m³ (21-23 July 1977), 140 larvae per 1,000 m³ (25-26 July 1978), 892 larvae per 1,000 m³ (26-27 July 1979), 1,608 larvae per 1,000 m³ (14-15 July 1980), 1,437 larvae per 1,000 m³ (15-16 June 1981), and 541 larvae per 1,000 m3 (6-8 July 1982 - Tables 18-20). The thermal regime of Lake Michigan in the vicinity of the study area appears to be one factor that affects the magnitude of larval alewife abundance The lowest annual abundance peak (140 larvae per 1,000 m³) during 8 years of entrainment sampling occurred in July 1978. Mean June and July temperatures in 1978 (13.7 °C and 14.1 °C, respectively) were 9% and 20% lower than the overall 1973-1982 mean temperatures for those months (Table 21). During 1975, the year with the greatest annual abundance peak (1,831 larvae per 1,000 m³), mean June (16.2 °C) and July (19.5 °C) water temperatures were approximately 7% and 10% greater than the 10-yr overall mean June and July temperatures.

Length-frequency distribution— The vast majority of entrained alewife have been yolk—sac larvae (<5 mm TL, Auer 1982). During 1975—1982 yolk—sac larvae accounted for between 61% (1979) and 94% (1975, 1980) of the total number of alewife entrained per year (Tables 22-24). This is not surprising, as increasing age brings increased mortality and probably an improved ability to avoid intake currents.

Alewife have an extended spawning period compared to many other species in our study area as is evidenced by the season of occurrence of yolk-sac larvae in entrainment samples. Yolk-sac larvae were first entrained in April (1977), May (1976, 1978), or June (1975, 1979-1982) and were present continuously until late July (1980) or August (all other years). The onset of spawning for alewife is closely related to water temperature (Threinen 1958, Cooper 1961). In 1976 and 1977 mean temperatures during March-May were higher than in any other year of entrainment sampling (Table 21). Accordingly, the earliest records of alewife yolk-sac larvae (10-11 May 1976 and 27-28 April 1977) occurred in those years (Bimber et al. 1984).

Although there are undoubtedly many factors that contribute to year-class strength in fishes, temperature is certainly an important one. Bimber et al. (1984) stated that the relative abundance of various length groups of alewife larvae entrained at the Cook Plant during 1975-1979 appeared to be related to water temperature, a pattern that seems to have held true during 1980-1982 as well. In 1980, a year of low overall abundance of alewife larvae, a number of upwellings occurred (Fig. 6) resulting in monthly mean temperatures from April to December that were consistently below the 10-yr average (Table 21).

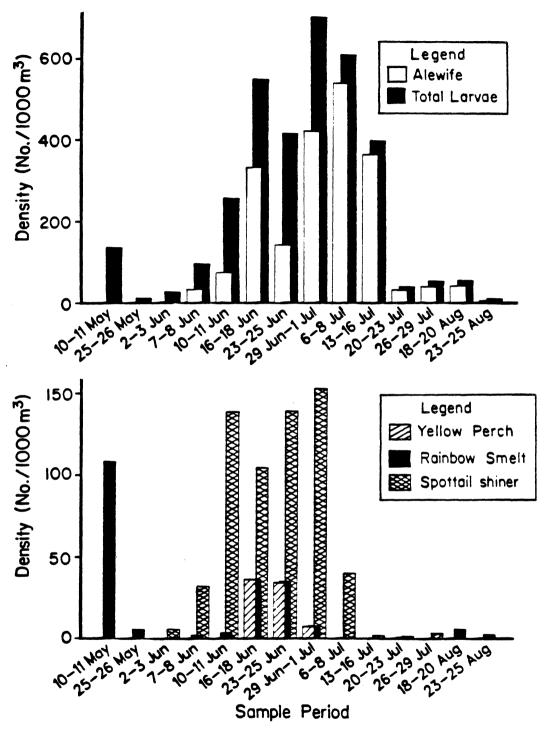

Figure 11. Density estimates of entrained fish larvae (no./1,000 m³) for alewife, spottail shiner, rainbow smelt, and yellow perch larvae, and fish eggs found in intake water used for condenser cooling at the D. C. Cook Plant, 1982.

Spawning apparently began late and ended early in that year as yolk-sac larvae were only present from 20-21 June to 30 July, which represents the shortest season of occurrence for alewife yolk-sac larvae in 8 years of entrainment sampling at the D. C. Cook Plant. Only 6% of entrained alewives were post-yolk-sac larvae in 1980.

In comparison with 1980, the 1981 temperature profile was generally warmer and was much more stable, with only one major upwelling in July (Fig. 7). Yolk-sac larvae first appeared on 8-9 June and were present in entrainment samples until 26-27 August. The upwelling in July may have extended the duration of spawning. Heufelder et al. (1982) showed that upwelling events in Lake Michigan prolonged the period of occurrence of newly hatched larvae. A small percentage of the alewife larvae entrained in 1981 (14%) and 1982 (23%) were post-yolk-sac larvae.

Diel distribution—Diel distribution of alewife larvae during 1980-1982 followed the same pattern established during 1975-1979 sampling, i.e., they were entrained in higher numbers at night than during the day (Tables 25-27). Examination of June-August entrainment samples during 1976-1982 via ANOVA showed that diel period was highly significant for alewife larvae densities (Table 9). The annual proportions of larvae entrained at night during 1980-1982 were 72%, 60%, and 74%, respectively. The dusk-midnight sampling period produced the greatest abundance of alewife larvae during 1980-1982. Alewife larvae entrained during dusk-midnight sampling represented 55% of the total number of alewife larvae entrained in 1980, 38% in 1981, and 42% in 1982.

Field Collections--

General trends— Alewife was the dominant fish species in field larvae samples during all 10 years of our study. Occurrence of alewife larvae in the study area was distinctly seasonal, corresponding to the period of warmer water temperatures, chiefly June through August or September (Figs. 6-8). In the beach zone, alewife larvae first appeared in April (1978), June (1973-1977, 1981, 1982), or July (1979) and were present every month until August (1982), September (1973, 1976, 1981), October (1974, 1975, 1979), or November (1977, 1978, 1980).

In 1977 and 1980-1982 alewife larvae appeared in open water samples I month earlier than in beach zone samples. In 1978 alewife larvae were collected in the beach zone in April and then not again until June when they were present both at the beach and in open water. In all other years, first appearance at beach and open water stations occurred during the same month (Figs. 12-16;

Table 25. Length-frequency distributions (sum of densities in no./1,000 m³) by diel period for major species entrained at the D. C. Cook Plant, southeastern Lake Michigan, 1980. Tables 28-37). Month of peak abundance in the beach zone was July in 7 of the 10 years of our study, August in 2 years, and June in 1 year.

In 5 of the 10 years of our study (1975, 1977-1980) peak abundances of alewife larvae at beach and open water stations occurred during the same month. Abundance peaks occurred earlier in open water than in the beach zone during 4 years (1973, 1974, 1981, 1982). In 1976 peak abundance occurred in June in the beach zone and in July at open water stations. June, July, and August samples combined accounted for 90-99+% of all alewife larvae collected in every year except 1979, when June-August samples provided only 79% of the annual alewife catch. but 1 year (1974) annual mean densities for alewife larvae were higher in the beach zone than in open water. Mean densities (no. per 1,000 m³) of alewife larvae in the beach zone for June-August samples combined during 1973-1982 were: 6,757, 793, 1,842, 2,497, 2,740, 1,132, 870, 3,124, 400, and 2,255, respectively (N usually = 36). Mean densities (no. larvae per 1,000 m³) in the open water zone for June-August samples combined during 1973-1982 were respectively: 1,099, 1,603, 689, 550, 129, 39, 572, 255, 138, and 439 (N usually = 180).

Mean densities differed significantly among years and among months at both beach and open water stations (ANOVA, p <0.0001 at both sets of stations for both year and month). Mean abundance did not differ significantly between Warren Dunes and the Cook Plant (ANOVA: beach - p = 0.3775; openwater - p = 0.5758), implying no detectable plant effect.

Depth distribution -- During 1980-1982 abundance of larval alewives at various depth contours followed the same pattern that was established during 1973-1979 sampling, i.e., alewife abundance generally declined with increasing bottom depth (Figs. 12-16, Table 38). Mean densities differed significantly among station depths (ANOVA; p <0.0001). On a yearly basis, alewife larvae abundance correlated more consistently with bottom depth than with any other parameter. Densities at beach and 6-m stations exceeded densities at 9-m stations in all years (1973-1982) and in all months except May 1981, when the only alewife larvae collected were at Cook station D (9 m) during night sampling. Alewife larvae were scarce at 21-m stations compared to high inshore abundances, presumably because spawning and hatching were concentrated inshore. Water temperature was shown to be an important correlate of larval fish abundance during 1973-1979 sampling, with greatest abundances usually occurring in the zone (beach or openwater) where water temperatures were the highest (Bimber et al. 1984). This held true in July and August during 1980-1982 when temperatures were higher and larval alewife

Table 28. Length-frequency distribution of alewife larvae (mean densities (no./1,000 m³)) caught near the D. C. Cook Plant. southeastern Lake Michigan, 1973. Length intervals are in mm (e.g., the 5-mm interval includes all larvae from 4.1 to 5.0 mm TL). Blanks indicate zero densities. Sample sizes are in parenthesis.

abundance was greater in the beach zone than in open water. However, during the early part of the season (May-June) no such pattern could be discerned.

Table 38. Mean densities (no. per 1,000 m³) of alewife larvae by depth contour (pooled over strata, month, and diel period) during 1980-1982. Values given represent June, July, and August samples combined. (No 21-m stations were sampled in 1982.) N = sample size.

9 m (60)	214	132	396
21 m (48)	115	4	ND

<u>Diel distribution</u>— There was not a consistent pattern of diel distribution for alewife larvae in the beach zone. During 4 years (1973, 1977, 1981, 1982) more larval alewives were caught during the day than at night at beach stations and during 6 years (1974-1976, 1978-1980) more were caught during night sampling. The diel factor was not significant for larval alewife densities in the beach zone over the 10-yr study period (ANOVA; p = 0.1195). Diel period was shown to be significant, however, when examined by month (p = 0.0007). Sampling in the beach zone produced more alewife larvae at night than during the day in June and July, but in August alewives were most abundant during the day.

In contrast, there was a consistent change in abundance of alewife larvae with diel period in the open water zone. Larval alewife densities were greater at night than during the day throughout the season in nearly every year (Tables 39-41). Only in June and July 1977 and 1980 and August 1978 did daytime catches exceed night catches. In two of those instances (July 1977 and August 1978) the reversal probably occurred because night samples were taken more than 2 wk later than day samples, on dates outside the period of peak alewife abundance. The Diel factor was shown to be highly significant (p <0.0001) for larval alewife densities in the open water zone.

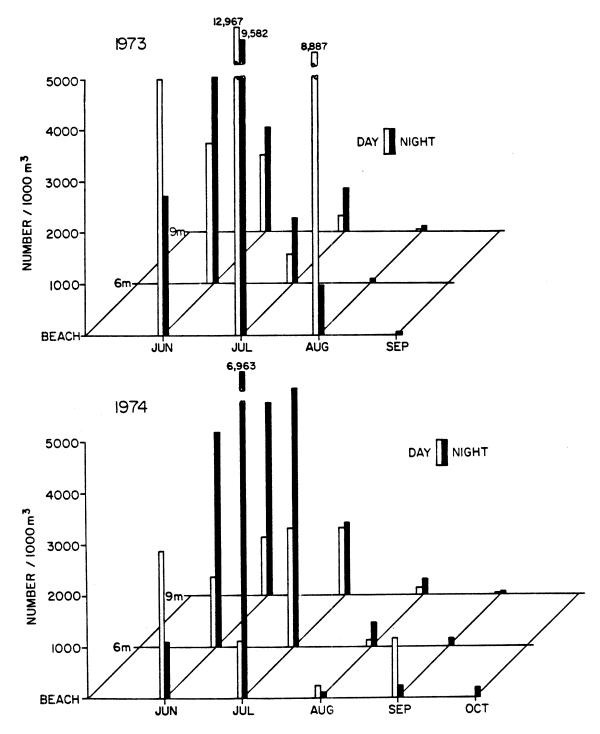

Figure 12. Mean densities (no./1,000 m³) of alewife larvae by depth contour, 1973 and 1974. Beach = stations A, B, and F; 6-m contour = stations C, G, and R; 9-m contour = stations D and H. (No 21-m stations were sampled in 1973 or 1974.)

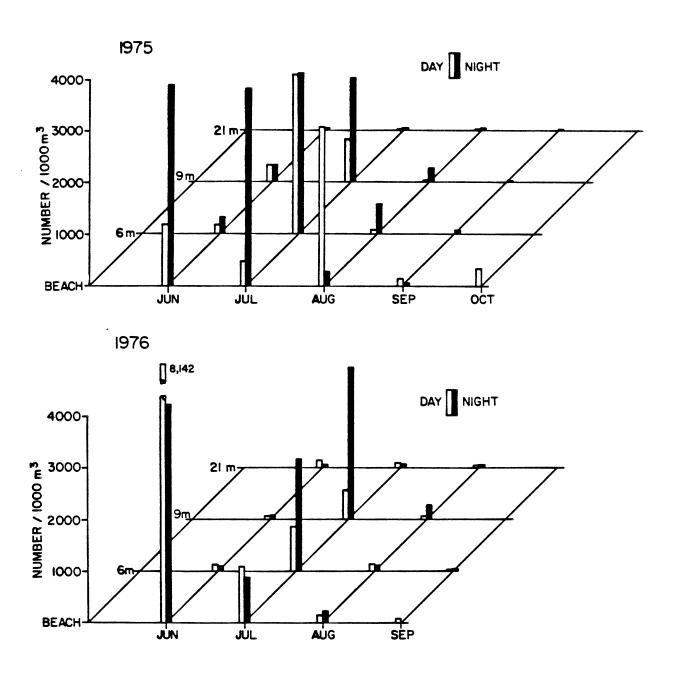

Figure 13. Mean densities (no./1,000 m³) of alewife larvae by depth contour, 1975 and 1976. Beach = stations A, B, and F; 6-m contour = stations C, G, and R; 9-m contour = stations D and H; 21-m contour = stations E and W.

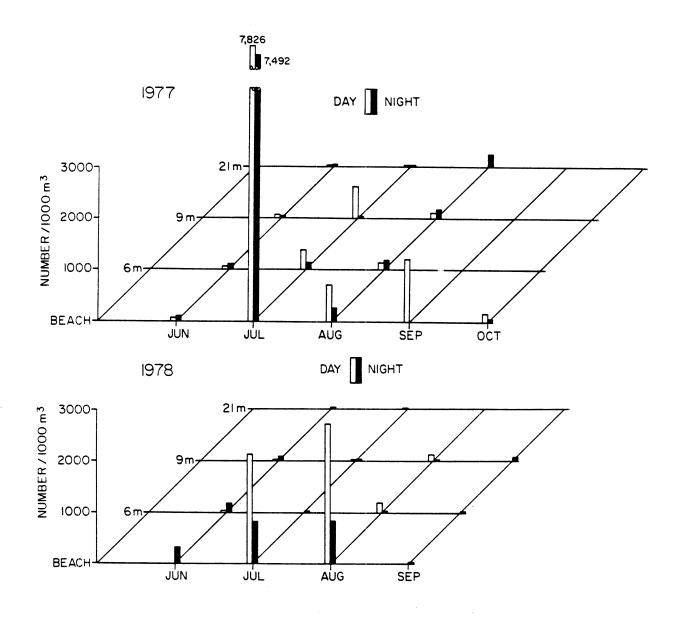

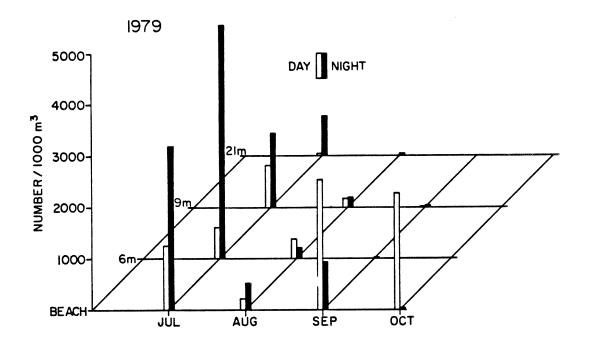

Figure 14. Mean densities (no./1,000 m³) of alewife larvae by depth contour, 1977 and 1978. Beach = stations A, B, and F; 6-m contour = stations C, G, and R; 9-m contour = stations D and H; 21-m contour = stations E and W.

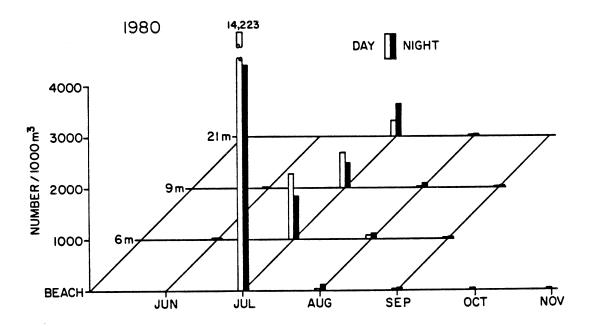

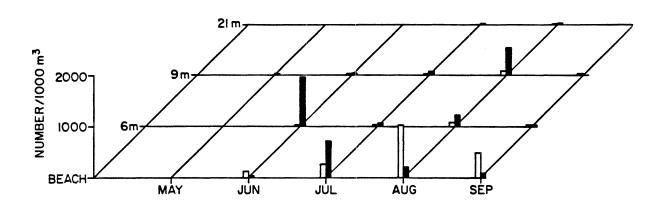

Figure 15. Mean densities (no./1,000 m³) of alewife larvae by depth contour, 1979 and 1980. Beach = stations A, B, and F; 6-m contour = stations C, G, and R; 9-m contour = stations D and H; 21-m contour = stations E and W.

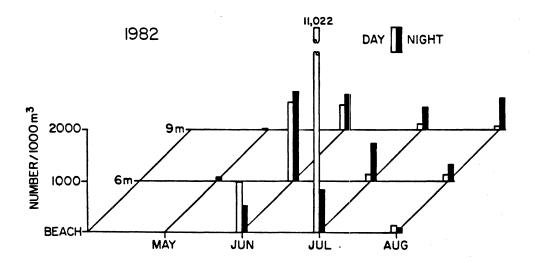

Figure 16. Mean densities (no./1,000 m³) of alewife larvae by depth contour, 1981 and 1982. Beach = stations A, B, and F; 6-m contour = stations C, G, and R; 9-m contour = stations D and H; 21-m contour = stations E and W. (21-m stations were not sampled after May, 1982.)

The most important source of the increased abundance of larval alewives at night was probably that they avoided nets more effectively in daylight. Avoidance capabilities increase as larvae grow and develop their swimming ability and vision (Houde 1969, Theilacker and Dorsey 1980). Our data provide evidence for daytime net avoidance as samples collected at night usually contained more large larvae than those collected during the day (Tables 39-41). Bimber et al. (1984) showed that during 1973-1979 the proportion of alewife larvae captured at night in the open water zone increased with body size, indicating that nighttime catches estimated abundance more reliably than daytime catches, at least for larger larvae. The same pattern was evident in our 1980-1982 data from the open water zone (Table 42).

Table 42. Night-to-day catch ratios (% caught at night) for different size groups of alewives in field samples during 1980-1982. Percentages are based on total densities (no. per 1,000 m³) which were summed across all samples and all years at 6-, 9-, and 21-m open water stations C, D, G, H, E, R, and W and beach stations A, B, and F. N = 1,308.

Habita	at
Open Water	Beach
55	28
78	13 6
	Open Water 55

The opposite was true in the beach zone however, as the proportion of larvae caught at night decreased sharply with increasing size (Table 42). The same trend was evident in data from the beach zone in 1973-1979 and it was suggested that the greater abundance of larger larvae in beach samples during the day may be the result of a daily migration between the beach and open water zones by larvae >8 mm TL resulting in few larvae present in the beach zone at night (Bimber et al. 1984, Jude et al. 1979b).

Length-frequencies— Seasonal changes in the length-frequency distribution of larval alewives helped show pulses of spawning and tracked growth. Length-frequency histograms for 1980-1982 (Fig. 17-19) showed the same three seasonal changes that were evident in 1973-1979, i.e., (1) mean length increased

through the season as larvae grew, (2) the abundance peak at the lower end of the distribution became less pronounced by August, as spawning declined and newly hatched larvae became scarce and, (3) the greatest range of sizes occurred in midsummer when both newly hatched and older larvae were present.

Spottail Shiner

Entrainment--

General trends— Approximately 67 million spottail shiner larvae were entrained at the Cook Plant during 1975-1982, making them the second-most-commonly entrained fish species (Table 13). Annual entrainment loss estimates ranged from 0.9 million (1976) to 28.2 million (1982) larvae. Although they were the second-most-abundant species in entrainment samples, spottail shiners only accounted for between 1.3% (1979) and 22.9% (1980) of total annual entrainment estimates. Overall, for the period 1975-1982, spottail shiner larvae represented 9% of the total projected entrainment loss.

The reduced vulnerability of spottail shiner larvae to entrainment compared with alewives probably results from several aspects of spottail shiner ecology as well as their relative abundance in the vicinity of the Cook Plant. Spottail shiner spawning is concentrated in nearshore waters (Tesar et al. 1985, Wells and House 1974) so peak hatching presumably occurs away from the realm of influence of the intakes (7-m depth contour). In addition, abundance of spottail shiner larvae in bottom sled tow samples taken at the Cook Plant in 1974 (Jude et al. 1979b) and at the J. H. Campbell Plant near Grand Haven, Mi. during 1977-1980 (Jude et al. 1981) suggests that they are largely demersal, further reducing their susceptibility to entrainment compared with the pelagic alewife larvae. Finally, spottail shiner adults were less abundant in the study areas than were alewife adults (Tesar et al. 1985) and as a result of that fact alone, we would expect fewer spottail shiner than alewife larvae entrained.

Spottail shiner larvae first appeared in entrainment samples in May (1981) or early to mid-June (all other years) and were present until late July (1977,1980), August (1975, 1978, 1979, 1981), September (1982), or even October (1976). Peak abundance of entrained spottail shiners generally occurred in June (1977, 1981, 1982) or July (1975, 1976, 1978, 1980), but sometimes occurred as late as August (1979). Greatest 24-h mean densities (number per 1,000 m³) during 1975-1982 were 93 (15-18 July), 8 (12-16 July), 106 (21-23 June), 10 (7-8 August), 10 (1-2 August), 732 (14-15 July), 134 (15-16 June), and 153 (29 June-1 July), respectively (Tables 18-20; Bimber et al. 1984). Greatest

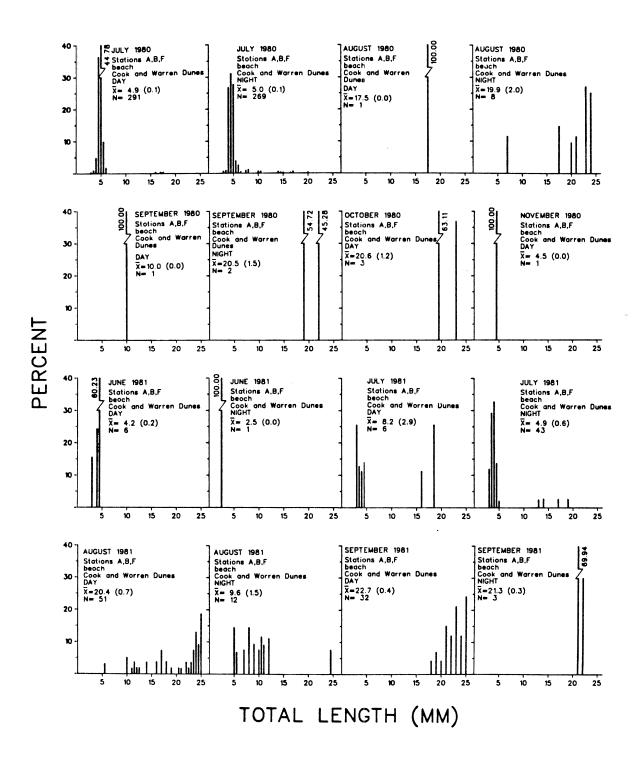

Figure 17. Length-frequency distribution of alewife larvae in the beach zone, 1980-1982.

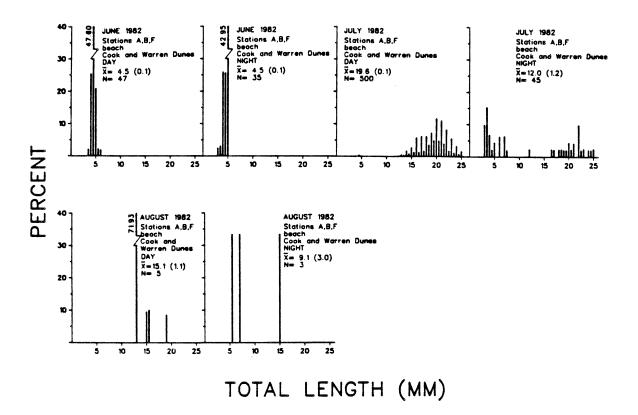

Figure 17. Continued.

individual sample densities (number per 1,000 m³) in each year were 354 (16 July 1975), 81 (4 August 1976), 511 (21 June 1977), 126 (19 July 1978), 111 (6 August 1979), 2,710 (15 July 1980), 471 (16 June 1981), and 932 (24 June 1982).

Spottail shiner larvae were more commonly entrained at night than during the day in every year of our study. Annual percentages of larval spottail shiners entrained during darkness were 90, 78, 90, 84, 82, 97, 76, and 96 for the years 1975-1982 respectively (Tables 25-27; Bimber et al. 1984).

Length-frequency distributions for spottail shiners entrained during 1980-1982 were very similar to 1975-1979 distributions. In 1980-1982 the smallest spottails collected in entrainment samples fell into the 3-mm interval (2.1-3.0 mm TL)

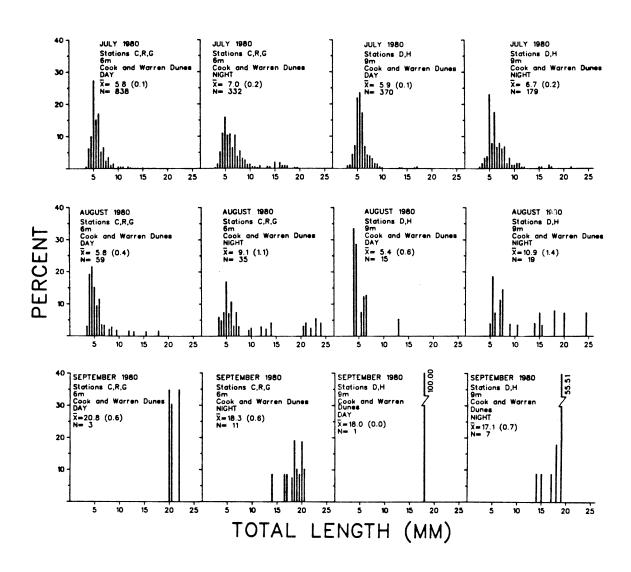

Figure 18. Length-frequency distribution of alewife larvae at 6- and 9-m stations, 1980-1982.

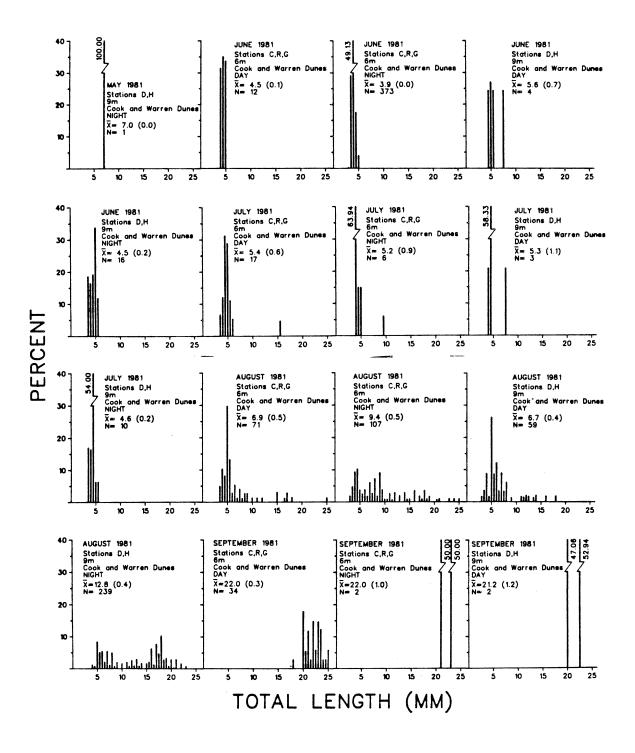

Figure 18. Continued.

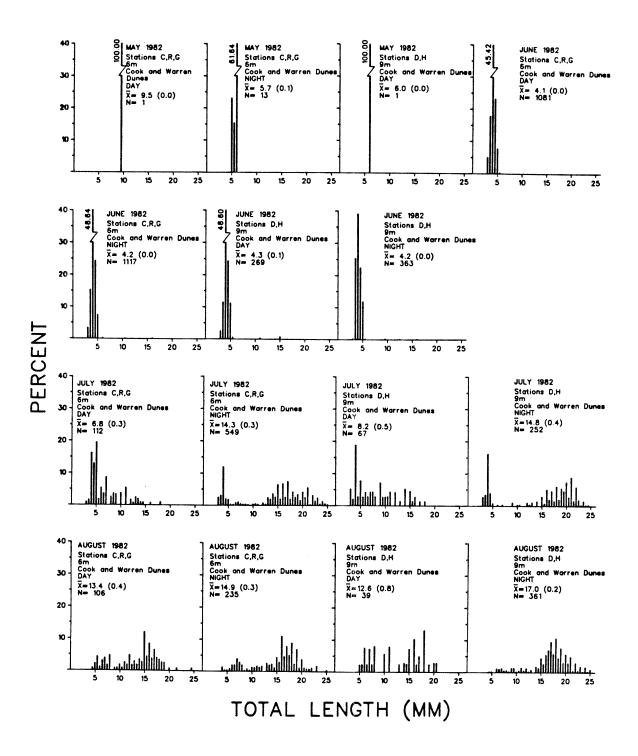

Figure 18. Continued.

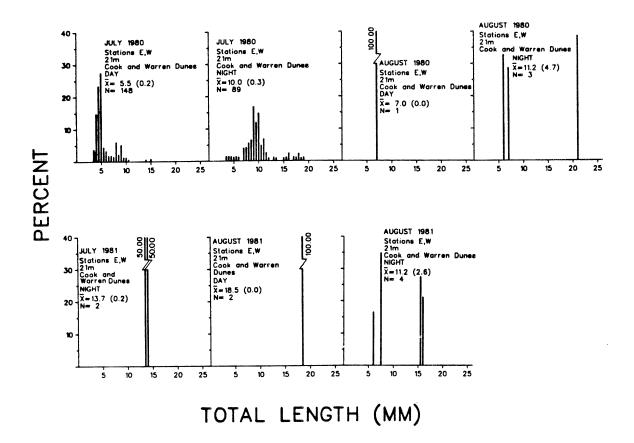

Figure 19. Length-frequency distribution of alewife larvae at 21-m stations, 1980-1981. (21-m stations were not sampled in 1982.)

and the largest within the 14-mm interval (13.1-14.0 mm) (Tables 25-27), but larger larvae were relatively rare. The majority (74%) of entrained spottail shiners were <5 mm TL, and therefore newly hatched. Spottail shiners entrained during 1975-1979 ranged in length from 2.1-3.0 mm to 11.1-12.0 mm with 73% measuring <5 mm (Bimber et al. 1984).

Field Collections--

General trends— Occurrence of larval spottail shiners in our study areas was sharply seasonal like that of alewife, and corresponded with the period of maximum water temperatures (Figs. 6-8). Spottail shiner larvae first appeared at beach

stations in June during all years except 1977, when they were not present until the July sampling period. June was the month of first appearance in the open water zone as well, except for 1977 (July) and 1981 (May). Peak abundances of spottail shiner larvae in the beach zone occurred in June (1973, 1975, 1976, 1978), July (1974, 1977, 1979, 1980, 1982), or August (1981). During 7 of the 10 years of our study spottail shiner abundance peaked in the open water zone during the same month as in the beach zone. In 1975, abundance at open water stations peaked during July, and in 1981 and 1982 during June. Spottail shiner larvae were present in beach zone samples until August of every year except 1974, when they were still found during September.

Densities of spottail shiner larvae in the beach zone differed significantly among years (ANOVA, p <0.0001). Geometric mean densities (number per 1,000 m³) for June-August night samples only, averaged over 1973-1982, were 41, 1,142, 518, 177, 41, 36, 487, 126, 309, and 86, respectively. It is possible that our once-per-month sampling program sometimes caught and sometimes missed the period of peak abundance. Densities of spottail larvae in nighttime beach zone samples did not differ significantly between Cook Plant and Warren Dunes stations during 1973-1982 (ANOVA, p = 0.8415), implying no detectable plant impact.

Spottail shiner larvae were considerably less abundant in open water than in the beach zone (Tables 43-52). At open water stations, relative abundance was estimated by the number of samples in which spottail shiner larvae occurred. Larvae were found in 12 (of 280) samples in 1974, 21 (of 380) samples in 1975, 9 (of 360) in 1979, 16 (of 360) in both 1980 and 1981, 14 (of 300) in 1982, and in 4 or fewer in other years (annual sample size = about 360). Most samples from open water stations contained no spottail shiner larvae, thus precluding comparisons of densities at beach and open water stations.

A decrease in abundance of spottail larvae with increasing depth was evident by comparing the number of samples containing spottail shiner larvae at different depth contours. During the period 1973-1982 (1975-1981 for 21-m depth), 6-m stations C and G (N = 16/mo) produced 55 such samples, 9-m stations D and H (N = 20/mo) produced 20, and 21-m stations E and W (N = 16/mo) produced 3.

More spottail shiner larvae were caught at night than during the day in all years at beach stations, and in all years except 1977 and 1978 at open water stations (Tables 53-55, Appendices 4-6; Bimber et al. 1984). Most daytime samples contained no spottail shiner larvae at all. During 1973-1982, 81% of the beach zone samples and 83% of the open water samples that contained spottail shiner larvae were collected at night. This

diel difference in abundance is attributed to net avoidance. No larvae larger than 8.0 mm TL were captured during day sampling in 1980-1982, while large larvae were relatively common at night (Tables 53-55), adding weight to the theory of daytime net avoidance. A similar pattern was observed during 1973-1979 (Bimber et al. 1984).

Spottail shiner larvae were abundant enough in the beach zone during 1980-1982 to show seasonal changes in size distribution, outlining the schedule of hatching and growth (Fig. 20). As in 1973-1979, newly hatched larvae (4-5 mm TL, Auer 1982) first appeared in June and were present until July or August (Figs. 6-8). Spottail shiner larvae were absent from beach zone samples from September and October probably because the hatching period had ended by that time, and most larvae had grown to a large enough size to effectively avoid our nets.

Rainbow Smelt

Entrainment--

Rainbow smelt larvae were the third-most-abundant larvae entrained, accounting for 4.8% of the total entrainment estimates of 35.2 million larvae during 1975-1982 (Table 13). Yearly entrainment estimates of rainbow smelt larvae ranged from 0.18 million larvae in 1977 to 18.5 million in 1982. High entrainment during 1980-1982 (33.1 million larvae over the 3 years) was due in part to the high abundance of rainbow smelt larvae in the inshore area during this period (Appendices 4-6). Relatively large quantities of water used for cooling during 1980-1982 (Table 14) also contributed to the high entrainment losses. Substantial increases in water pumped through the intake occurred in May and June when rainbow smelt larvae were most abundant in the inshore area. In 1975, despite the relatively abundant populations of rainbow smelt larvae, only a moderate entrainment loss of this species (1.3 million larvae) occurred due to relatively low amounts of water used for cooling. Low entrainment of rainbow smelt larvae during 1976-1979 resulted from scarcity of larvae in the inshore water.

As was found with field distribution, entrainment of rainbow smelt larvae occurred from April to August. Monthly entrainment estimates of rainbow smelt larvae ranged from 0 to 10.8 million. Peak entrainment was observed in April during 1976, May during 1975 and 1980-1982, June during 1978, and July during 1977 and 1979 (Tables 15-17; Bimber et al. 1984). Most larvae were entrained during May. In years when rainbow smelt larvae were abundant, as in 1975 and 1980-1982, however, substantial numbers were also entrained during June. Entrainment was generally low during July and August. Peak entrainment densities during a 24-h

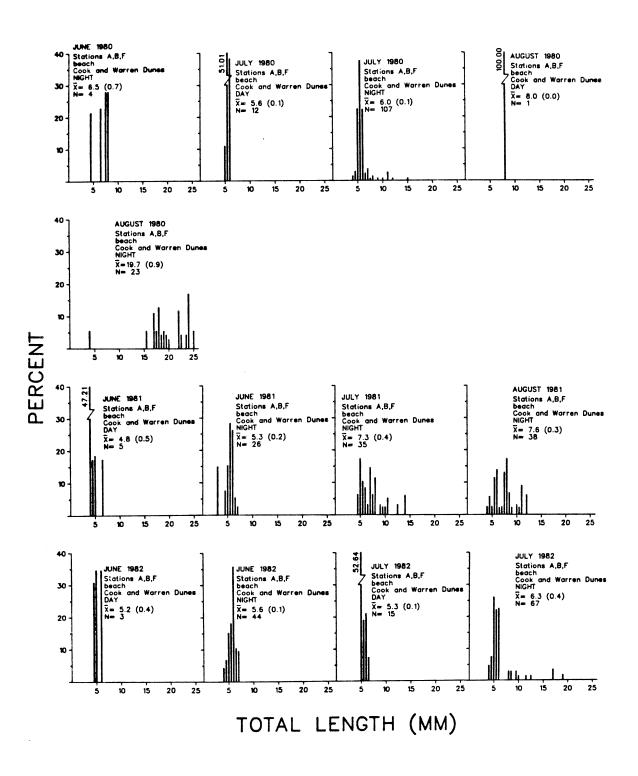

Figure 20. Seasonal growth of spottail shiner larvae in the beach zone, 1980-1982.

period for each year varied greatly, ranging from 3 larvae/1,000 m³ during 6-7 July 1977 to 158 larvae/1,000 m³ during 10-11 May 1982.

Like many other species of fish, rainbow smelt are most susceptible to entrainment soon after hatching. During 1975-1982, with the exception of 1977 and 1982, larvae ≤ 8 mm represented more than 50% of the total number of rainbow smelt larvae entrained (Tables 25-27; Bimber et al. 1984). smaller larvae were entrained over a short period of time, mostly during May. Entrainment of larvae ≤8 mm lasted 1 to 2 wk during 1976, 1977, 1979, 1980, and 1982 and 3 to 4 wk in 1975, 1978, and Rainbow smelt larvae ≥8 mm were entrained mostly during June and July. Larger larvae (>17 mm) were entrained in substantial numbers, accounting for 14 to 78% of total rainbow smelt larvae entrainment during 1975-1982; whereas, larvae 9-17 mm made up only from 0 to 25% of the total number of rainbow smelt entrained. Relatively higher susceptibility of larvae >17 mm to entrainment may be due to their concentration near intake structure depths. Rainbow smelt larvae were entrained more commonly at night than during the day.

Field Collections--

Rainbow smelt larvae occurred in field samples over a short period in spring and summer. During 1973-1982, rainbow smelt larvae were generally first collected during May, except in 1973 when they first appeared during April (Appendices 4-6; Bimber et al. 1984). Rainbow smelt larvae were also found in entrainment samples during April in 1976, 1977, and 1979. These data indicated that early hatching of rainbow smelt larvae occurred more commonly near the Cook Plant than near the Campbell Plant (Jude et al. 1982, Tin and Jude 1983). Abundance of rainbow smelt larvae generally peaked in May and began to decline in Monthly densities ranged from 0 to 424 larvae/1,000 m³ in May and from 0 to 149 larvae/1,000 m³ in June during 1973-1982. No rainbow smelt larvae were collected in June 1974 and 1975. Rainbow smelt larvae were scarce in summer. They were collected in July, only during 1978-1980 and 1982, and in August, only during 1979-1982 (Tables 56-65).

Rainbow smelt larvae were generally more abundant in the beach zone than in open water during May, except in May 1976, 1977, and 1981 when catches were higher in the open water than at beach stations. During May 1973-1975 and 1978-1982, densities ranged from 16 to 957 larvae/1,000 m³ in the beach and from 1.5 to 150 larvae/1,000 m³ in the open water. During June-August, more larvae were collected in the open water than in the beach zone (Tables 56-65, Appendices 4-6). These data suggested that rainbow smelt first hatched in the beach zone and moved to deeper water soon after hatching. This suggestion was supported by

Table 56. Length-frequency distribution of rainbow smelt larvae (mean densities (no./1,000 m³)) caught near the D. C. Cook Plant, southeastern Lake Michigan, 1973. Length intervals are in mm (e.g., the 5-mm interval includes all larvae from 4.1 to 5.0 mm TL). Blanks indicate zero densities. Sample sizes are in parentheses.

length-frequency data (Tables 56-65). In years with enough fish to draw conclusions, 1974, 1975, and 1977-1982, larvae taken at beach stations averaged slightly smaller than those collected in open water (Tables 56-65). In 1974, when sampling was conducted weekly in May, rainbow smelt larvae appeared in the beach zone 2 weeks earlier than in open water. Absence of rainbow smelt larvae at the beach in May 1976 and 1977 probably resulted from dispersal of all larvae to offshore areas before May sampling.

Beach and open water catches varied considerably over the study period. The ANOVA of data collected in May during 1974-1975 and 1980-1982, showed significant density differences among years both in the beach zone and in open water (p = 0.0001). Highly variable densities in May were probably due to variations in the start of the spawning run (Rupp 1959), incubation period of rainbow smelt eggs at different temperatures (McKenzie 1964), and rapid dispersal of rainbow smelt larvae from the hatching site (Tin and Jude 1983). Data from 1976 to 1979 were not used in the statistical analysis due to low catches. Beach catches during 1974, 1975, and 1980-1982 did not differ significantly between Cook and Warren Dunes stations (ANOVA, p = 0.48). In the open water, densities at Cook were significantly higher than at Warren Dunes (ANOVA, p = 0.0015) when preoperational and operational years were combined (1974, 1975, and 1980-1982). This significance was due to the unusually high catches at 6 and 9 m during May 1974 (Bimber et al. 1984). During operational years (1975 and 1980-1982), however, no significant difference between Cook and Warren Dunes open water stations (C and D vs. G and H) was observed (Kruskal-Wallis, p = 0.02). These data suggested no plant impact on larval rainbow smelt populations.

Rainbow smelt larvae ranged from 3.5 to 8 mm during May and from 4.5 to 22 mm during June. Near the Campbell Plant, 105 km north of the Cook Plant, substantial hatching of rainbow smelt larvae took place in late June (Tin and Jude 1983). Scarcity of newly hatched rainbow smelt larvae (<6 mm) in June during 1973-1982 (Tables 56-65) suggested little late hatching near the Cook Plant. Most larvae collected in June were 11-15 mm.

Rainbow smelt larvae were equally abundant at 6- and 9-m stations, but less common at 21-m stations. During 1973-1974 and 1977-1982, rainbow smelt larvae densities were 67 larvae/1,000 m³ at stations C and G (6 m) and 50 larvae/1,000 m³ at stations D and H (9 m). The ANOVA, however, showed no significant difference in densities between the two depths (p = 0.024). Substantially lower densities (0.7 to 8 larvae/1,000 m³) were observed at 21 m (stations E and W) during 1980, 1981, and 1982. Rainbow smelt larvae occurred nearly uniformly through the water column at 6- and 9-m stations, except for their absence from the surface in the day time. Rainbow smelt were generally more abundant in night samples than during the day (Tables 66-68).

Yellow Perch

Entrainment--

During 1975-1982, yellow perch larvae accounted for 1.8% (13.4 million) of total entrainment estimates. Yearly entrainment estimates fluctuated considerably, ranging from 38,000 larvae in 1976 to 5.0 million larvae in 1982 (Table 13, Fig. 5). In most cases, the number of yellow perch larvae entrained appeared to be related to larval yellow perch abundance in inshore water. Low entrainment generally occurred during years when low larval yellow perch densities were observed in field samples (1975, 1976, 1979, and 1980), whereas, high entrainment rates occurred during periods of high larval yellow perch abundance (1977 and 1982). Substantial numbers of yellow perch larvae were entrained, however, in 1978 and 1981 when low larval yellow perch populations were observed in inshore areas.

Yellow perch larvae were found in entrainment samples from April to August, with most being observed in June. Perch larvae were entrained in April, only during 1975 and 1976, and in May, only during 1977, 1978, 1980, and 1981. They occurred in June entrainment samples every year during 1975-1982. Monthly entrainment estimates ranged from 0 to 200,000 larvae during April and May, and from 29,000 to 4.9 million during June (Tables 15-17; Bimber et al. 1984). Entrainment continued at low levels in July every year, except in July 1982 when no perch larvae were entrained. No yellow perch larvae were found in August entrainment samples, except in 1982. Densities in 24-h entrainment samples were generally highest during June (Figs. 9-11), except in 1975, when the peak occurred in July. Peak densities in a 24-h period ranged from 0.1 to 74 larvae/1,000 m³.

Although larval yellow perch collected in entrainment samples during 1975-1982 ranged in length from 3 to 11 mm, the vast majority (98%) were newly hatched (≤7 mm TL). Elevated susceptibility to entrainment for hatchlings compared with older, larger larvae, occurs for many fish species, particularly yellow perch larvae, which are planktonic when newly hatched (Houde 1969). Decline in entrainment rates as larvae attain greater size is likely the result of a combination of factors including increased avoidance capabilities, a possible shift in distribution away from the influence of intakes, and natural mortality. Since newly hatched yellow perch larvae are usually 5 to 6 mm (Auer 1982) and normally grow about 0.5 mm per day (Mansueti 1964), the largest perch larvae entrained were less than 2 wk old.

More yellow perch larvae were entrained at night than during the day in all years, except 1976 and 1981. Their ability to avoid intakes during the day and less so at night probably contributed to this phenomenon. In 1975, 1978, 1979, and 1980, greatest mean annual density occurred during dusk-midnight sampling. Midnight-dawn samples showed greatest annual mean density of yellow perch larvae in 1977 and 1982. Greatest annual mean density in 1976 and 1981 occurred during noon-dusk sampling. In 1976, the year of lowest total projected entrainment for yellow perch, no yellow perch larvae were entrained at night. Densities of entrained yellow perch were generally lowest during dawn-noon sampling.

Field Collections--

The season of occurrence of yellow perch larvae was usually shorter and began earlier than those of alewife and spottail shiner. Yellow perch larvae were first collected during April in 1973 and 1978, May in 1979-1981, June in 1974-1977 and 1982 (Figs. 6-8; Bimber et al. 1984). Since adult yellow perch in the study area ordinarily did not attain spawning conditions until May, the early larvae probably entered Lake Michigan from inland lakes or rivers, where spawning begins sooner than in Lake Michigan (Perrone et al. 1983). Yellow perch larvae were generally scarce during April and May, with densities ranging from 0 to 22.6 larvae/1,000 m³ (Appendices 4-6). They were found in April, only during 1973 and 1978, and in May, only during 1973 and 1978-1981. The month of peak abundance was generally June as was observed in 1973, 1975, 1977-1979 and 1982. Highest densities occurred during May in 1980 and 1981, and during July in 1976 (Appendices 4-6; Bimber et al. 1984). Peak monthly densities ranged from 0.9 larvae/1,000 m3 in July 1976 to 205 larvae/1,000 m³ during June 1982. Larvae were scarce during July and August (Tables 69-78), presumably due to net avoidance.

During April, yellow perch larvae were taken only in open water. During May, they were more common in the beach zone than in open water. During June, more larvae were collected in the open water, except in 1978, 1979, 1980, and 1981 when higher densities were observed at beach stations. Larval yellow perch densities in the beach varied greatly, ranging from 0 to 91 larvae/1,000 m³ in May and from 0 to 324 larvae/1,000 m³ in June. In the open water, yellow perch larvae occurred in May samples only during 1981, but were collected in June every year during 1973-1982. All yellow perch larvae caught in July and August were found in open water.

Densities of yellow perch larvae in open water during June were significantly different among years (ANOVA, p <0.0001). This significance was due to highly variable open water densities (7 to 167 larvae/1,000 m³). The ANOVA was based on data collected during 1973, 1974, and 1977-1982. Catches of yellow perch larvae during 1975 and 1976 were too low for statistical

Table 69. Length-frequency distribution of yellow perch larvae (mean densities (no./1,000 m²)) caught near the D. C. Cook Plant, southeastern Lake Michigan, 1973. Length intervals are in mm (e.g., the 5-mm interval includes all larvae from 4.1 to 5.0 mm TL). Blanks indicate zero densities. Sample sizes are in parentheses.

analysis. Larval yellow perch abundance in preoperational and operational years followed no patterns attributable to plant operations. Yellow perch larvae were scarce at Warren Dunes and Cook stations in preoperational year 1973 and operational years, 1975, 1976, 1978-1981. They were abundant in both areas in 1974, 1977, and 1982. The Kruskal-Wallis test revealed no significant difference in open water densities in June between preoperational years (1973, 1974) and operational years (1977-1982) (p = 0.155). During operational years (1977-1982), open water densities at Cook were not significantly different from those at Warren Dunes stations (Kruskal-Wallis, p = 0.768). Thus we infer no plant impact on the distribution of yellow perch larvae.

Yellow perch larvae were equally common at 6- and 9-m stations. The ANOVA showed no significant density difference between 6-m stations (C and D) and 9-m stations (D and H) during June 1973, 1974, and 1977-1982. Mean densities at 6- and 9-m stations over the period 1973, 1974, and 1977-1982 were respectively 63 and 50 larvae/1,000 m³. At 6- and 9-m stations, abundance was similar at all depth strata, except for the deepest stratum, where yellow perch larvae were less frequently taken. Abundance of yellow perch larvae also declined at greater depth contours. At stations E and W (21 m) mean density was only 5 larvae/1,000 m³ during June 1975-1981.

In the beach zone, more yellow perch larvae were caught at night than during the day, due probably to net avoidance during daylight. In the open water, larval fish densities were also generally higher at night than during the day (Tables 79-81). However, no significant difference between day and night densities in the open water during 1973, 1974 and 1977-1982 were found (ANOVA, p = 0.395).

Yellow perch larvae collected ranged from 3.5 to 10.5 mm, most being 7.5 mm and smaller (Tables 69-81). Increased net avoidance by larger larvae probably contributed to the complete absence of larvae larger than 10.5 mm from field samples as well as scarcity of larvae from July samples. Only 5% of the yellow perch larvae caught in field samples were >7.5 mm TL. Survival rate from the egg to 8 mm in Oneida Lake is about 5-14% (Clady and Hutchinson 1975), so that net avoidance was not the sole cause of rarity of larger larvae. In fact, we believe that juvenile and adult alewife, which are common at this time in inshore waters, preyed on a substantial number of newly hatched yellow perch (Jude and Tesar 1985). Yellow perch larvae are passive at this stage (Houde 1969) and would be easy prey for alewives. In fact when alewives declined in 1980, yellow perch larvae densities increased dramatically. Juvenile and adult yellow perch populations have subsequently rebounded as a result of the alewife decline (Jude and Tesar 1985).

Table 79. Length-frequency distributions (mean densities in no./1,000 $\rm m^3$) by diel period for yellow perch larvae caught near the D. C. Cook Plant, southeastern Lake Michigan, 1973-1976. Length intervals are in mm (e.g., the 5-mm interval includes all larvae from 4.1 to 5.0 mm TL).

Less Abundant Species

Fourteen species of larval fishes were captured in small numbers in field samples during 1973-1982. These included burbot, trout-perch, common carp, johnny darter, deepwater (formerly fourhorn) sculpin, slimy sculpin, ninespine stickleback, quillback, gizzard shad, emerald shiner, and unidentified members of the sucker, minnow, sculpin, and herring families. All these species, except gizzard shad, emerald shiner, and unidentified sucker larvae, were also collected in entrainment samples. In addition, entrainment samples also contained small numbers of mottled sculpin and unidentified darter larvae. Among the less abundant species, trout-perch and johnny darter larvae were most frequently observed both in field and entrainment samples. Common carp and burbot larvae were more common in field than in entrainment samples. In contrast, slimy sculpin larvae occurred more frequently in entrainment than in field samples.

Burbot--

Burbot larvae were collected in field samples during 1975, 1976, and 1978-1982. The highest number of samples containing burbot larvae in any year was seven (1982). Densities in a sample ranged from 16 to 512 larvae/1,000 m³. Most burbot larvae were collected during April and May. A few burbot larvae were found in June during 1979 and 1980. These data agreed with Mansfield et al. (1983) who reported burbot larvae hatched during late April and May in Lake Michigan. Burbot larvae were found in water up to 21 m deep, but their densities tended to be higher in the beach zone than in open water. Burbot larvae we collected were mostly 3.5-5.0 mm, i.e., newly hatched (Mansfield et al. 1983). A 6-mm larva was caught in 1974 and a 14-mm larva in 1976.

Burbot larvae were entrained only in 1976, 1978, and 1982. Entrainment estimates for the 3 years were 0.46 million larvae. Burbot larvae were found in entrainment samples during March, April, and June. They ranged from 3.5 to 6 mm TL.

Trout-perch--

Trout-perch larvae were collected every year from 1974 to 1982. Although juvenile and adult trout-perch were common in the study area, larval trout-perch were generally scarce. Trout-perch larvae were found only in one to three samples every year. Densities of larvae in a sample generally ranged from 15 to 149 larvae/1,000 m³, except for a 1977 sample which contained 1041 larvae/1,000 m³. Trout-perch larvae occurred from May to

October, suggesting that trout-perch had the longest spawning and hatching season of any species collected in this study. Trout-perch larvae were dispersed throughout the study area, but were more commonly found in the beach zone than in open water. More trout-perch larvae were collected at Cook than at Warren Dunes. Of the 14 samples containing trout-perch larvae, only four were taken at Warren Dunes stations. Most trout-perch larvae were caught at night (Appendices 4-6). Trout-perch larvae ranged from 4 to 6 mm TL, except an 8-mm larva collected in May 1976.

Entrainment estimates for trout-perch larvae during 1975-1982 (4.5 million larvae) accounted for 0.6% of total entrainment. Trout-perch larvae were entrained every year; the highest projected losses were observed in 1975 (1 million larvae) and 1982 (1.4 million larvae). Due to the very long spawning season of trout-perch, entrainment of larval trout-perch took place over an extended period. Trout-perch larvae were normally entrained from June to October, but in 1976 they occurred in February and November entrainment samples (Appendices 1-3; Bimber et al. 1984). Most trout-perch larvae were entrained during August, September, and October (Tables 15-17; Bimber et al. 1984). The number of entrainment samples containing troutperch larvae ranged from 1 in 1978 to 9 in 1982. Greatest densities in individual samples were: 46 larvae/1,000 m³ (October 1975), 17 larvae/1,000 m³ (17 July 1976), 42 larvae/ 1,000 m³ (22 August 1977), 35 larvae/1,000 m³ (1 August 1978), 75 larvae/1,000 m³ (27 June 1979), 78 larvae/1,000 m³ (20 June 1980), 42 larvae/1,000 m³ (16 June 1981), and 46 larvae/1,000 m³ (6 October 1982). Most larvae were entrained at night. Only 5 of the 45 samples containing trout-perch were collected during the day. Entrained trout-perch larvae ranged from 4.0 to 19.3 mm TL.

Johnny Darter--

Johnny darter larvae were collected during 1976, 1977, and 1979-1982. Generally only one to three field samples contained johnny darter larvae each year; in 1982 however, johnny darter larvae occurred in nine samples. Johnny darter larvae were caught mostly during June and July; a few occurred during August in 1980 and during April in 1982. Johnny darter larvae were found mostly in open water. Of the 21 samples containing johnny darter larvae, only three were taken in the beach zone. More johnny darter larvae were caught at Cook than at Warren Dunes stations (Appendices 4-6). In the study of fish populations near the J. H. Campbell Plant, Jude et al. (1982) attributed the higher abundance of johnny darter at plant stations compared with reference stations to the presence of rock riprap at the intake and discharge structures. Densities of larvae in a sample generally ranged from 13 to 150 larvae/1,000 m³. In 1977,

however, a density of 1,041 larvae/1,000 m³ was observed in the beach zone. Most johnny darter larvae we collected were newly hatched (4-6 mm TL).

Johnny darter larvae were entrained in every year except 1980. Entrainment estimates (3.4 million larvae) accounted for 0.4% of projected total entrainment (Table 13). Entrainment was highest in 1977, 1978, and 1982 (Table 13). Johnny darter entrainment occurred during June, July, and August; most larvae were entrained during June. The number of entrainment samples containing johnny darter larvae ranged from one in 1975 to nine in 1977. Densities of larvae in individual samples ranged from 15 to 185 larvae/1,000 m³. Entrained johnny darter larvae ranged from 4 to 18 mm TL.

Common Carp--

Common carp larvae were collected in field samples during 1975, 1976, 1978, 1980, and 1982. They were abundant in 1975, 1976, and 1982, with peak densities in a sample of 2,505 larvae/ 1,000 m³, 11,814 larvae/1,000 m³, and 5,632 larvae/1,000 m³ respectively. During 1978 and 1980, the highest density observed was 144 larvae/1,000 m3. Common carp larvae occurred from June to August, being most common in July. In 1982 a few common carp larvae also appeared in April (Appendix 6). Common carp larvae had never been collected in the study area during preoperational During operational years, they were found mostly at Cook stations. Of the 23 samples containing common carp larvae, only two were collected at Warren Dunes. These data suggest that common carp spawning took place at Cook Plant stations during operational years and we attributed this to the warm water plume and currents produced by the heated discharge of the Cook Plant. Thus common carp spawning at the Cook Plant was a clear plant effect. Common carp larvae were collected at Warren Dunes at relatively low densities (31 larvae/1,000 m³ and 83 larvae/1,000 These larvae may have drifted from the Cook Plant area. At Cook stations, densities of larvae were substantially higher in the beach zone than in open water (Appendices 4-6), suggesting that carp spawning probably took place mostly in shallow water. Common carp larvae ranged from 4.0 to 7.4 mm TL.

Common carp larvae were found in entrainment samples from 1976 to 1981. Entrainment estimates during this period (0.9 million larvae) were relatively low. Yearly entrainment estimates ranged from 0.02 million larvae in 1977 to 0.3 million larvae in 1979. During 1975 and 1982 common carp larvae were abundant in Lake Michigan, but were completely absent from entrainment samples. In contrast, some common carp larvae were entrained during 1977 and 1981 when none were caught at Lake Michigan stations. Common carp larvae were collected in

entrainment samples during June, July, and August. They were found in three samples in 1976, one sample in 1977, two samples in 1978, six samples in 1979, one sample in 1980, and three samples in 1981. Densities in a sample ranged from 11 to 66 larvae/1,000 m³. A comparable density range (15 to 79 larvae/1,000 m³) was observed in field samples collected at open water stations. Entrained carp larvae ranged from 4.1 to 7.6 mm TL. Few juveniles were collected, suggesting high mortality of common carp larvae.

Sculpins--

Slimy sculpin larvae were collected in Lake Michigan only during 1975, 1980, and 1982. All larvae were taken during June at open water stations (Appendices 4-6). Densities of larvae in a sample ranged from 17 to 44 larvae/1,000 m³. More larvae were caught at Cook than at Warren Dunes stations, suggesting that rock riprap at the intake and discharge structures probably attracted spawning slimy sculpins. Slimy sculpin larvae were entrained every year except 1979. Estimated total entrainment of slimy sculpins was 2.5 million larvae during 1975-1982. Yearly entrainment estimates ranged from 0.02 million in 1977 to 1 million in 1981 (Table 13). Slimy sculpin larvae were entrained during June, July, and August. They measured from 6.0 to 9.3 mm TL.

Mottled sculpin larvae were never collected at Lake Michigan stations during 1973-1982. They were, however, entrained in all operational years except 1978 and 1980. Entrainment estimates for mottled sculpin larvae (1.1 million) were substantially lower than those for slimy sculpins. Mottled sculpin larvae were entrained only during May and June. Entrained larvae ranged from 6.0 to 9.2 mm TL.

Slimy sculpins and mottled sculpins are very similar in appearance as larvae and an accurate fin-ray count is essential to separate the two species correctly. Unidentified sculpin larvae were either slimy or mottled, but due either to their deteriorated physical condition or extremely early stage of development, they could not be identified with certainty. Unidentified sculpin larvae occurred in field samples only during 1978. They were found in entrainment samples every year during 1975-1982. Projected total entrainment of unidentified sculpin larvae was 2.5 million. Larvae were entrained during May, June, and July.

Deepwater sculpin larvae were caught at Lake Michigan stations during 1978-1981. They occurred only during April and May. All larvae we collected were taken in open water, with densities ranging from 17 to 65 larvae/1,000 m³. Deepwater

sculpins were entrained only during 1978 and 1979. Projected entrainment for the 2 years was 0.19 million larvae. Entrainment of deepwater sculpins occurred during March and June.

Ninespine Stickleback--

Ninespine stickleback larvae were caught at Lake Michigan stations only during 1974. They occurred in entrainment samples in 1978, 1980, 1981, and 1982. The total entrainment estimate for ninespine stickleback was 0.6 million. Larvae were entrained from June to September.

Unidentified Minnows--

Unidentified minnow larvae were found in field samples only during 1978 and 1981. They occurred in entrainment samples during 1977 and 1979-1982. Projected total entrainment of unidentified minnow larvae was 2.4 million. Highest yearly entrainment (1 million larvae) was observed in 1982. Unidentified minnow larvae were entrained from April to August.

Miscellaneous Species--

Quillback larvae were caught in two field samples during May 1980 and in one field sample during June 1982. This species was entrained during April 1977 and May 1981. Total entrainment estimate for quillback larvae was 0.6 million. Unidentified coregonid larvae were collected in Lake Michigan samples during August 1978 and in entrainment samples during May 1977. Gizzard shad larvae occurred in field samples in July 1982, emerald shiner during July 1981, and unidentified sucker larvae during May 1978. Entrainment samples taken during 1975-1982, however, never contained these three species. An unidentified darter larva was entrained during June 1977.

FISH EGGS

Introduction

Fish eggs collected at the Cook Plant were not identified to species. However, the probable species composition of the eggs can be shown by their distribution and seasonal occurrence. Entrained fish eggs in January and February were probably those of burbot, which spawn in midwinter under the ice. Fish eggs were most abundant in June and July, and the predominant spawning fish then are alewife, spottail shiner, and yellow perch. Yellow perch eggs remain in a gelatinous mass on the lake bottom while

incubating, so we would not collect them in plankton net tows. Spottail shiner eggs are demersal and adhesive (Auer 1982) so we would be unlikely to collect them, except in beach tows when conditions were somewhat turbulent. Therefore, most eggs in our samples, and probably virtually all those taken in open water during summer, were those of alewife. Alewife eggs are somewhat demersal, but not so much as those of spottail shiner (Auer 1982), so they probably sink slowly enough to be collected by plankton nets. Some large fish eggs (few in number) entrained during October and November may have been those of trout or salmon, which spawn in the fall.

Analysis of variance was applied to fish egg data for entrainment samples (1975-1982), beach samples (1973-1982), and open water samples (1974-1982 - see METHODS - FIELD LARVAE - Statistical Analyses for details). Many interactions were significant in the field egg ANOVA, particularly those including Year. Significant interactions interfere with analysis; however, significant factors are reported here despite interactions.

Entrained Eqqs

Annual Estimates--

Estimated entrainment loss of fish eggs was 3.335 billion during 1980, .996 billion during 1981, and 7.005 billion during 1982 (Table 13). Egg entrainment during 1980 and 1982 was higher than the 8-yr (1975-1982) average of 2.863 billion. The 1981 loss was below average and was the lowest since 1975. The 7 billion fish eggs estimated entrained in 1982 represented the highest yearly estimate of the 8 years of plant operation. June water volume pumped by the plant was higher in 1982 than other years (Table 14). As June is the month of peak fish egg densities, high pumping rates were most influential on estimates that month. Alewife larvae were fairly abundant in entrainment samples in 1982, but not as strikingly abundant as fish eggs, when year-to-year patterns are compared (Table 13).

Seasonal Abundance--

Fish eggs were entrained during most months, 1980-1982. Eggs entrained during January and February were probably burbot eggs and were usually few in number, except for 102 million estimated entrained during those months in 1982. Generally a few million eggs per month were entrained during early spring, with densities below 100 eggs/1,000 m³. A notable exception was the period 3 April-3 May 1982 when 1.135 billion eggs were entrained and mean densities exceeded 1,000 eggs/1,000 m³ several times. These were most likely rainbow smelt eggs. Peak egg entrainment

occurred during June 1980 (2.6 billion), 1981 (470 million), and 1982 (4.96 billion) (Tables 15-17). July egg entrainment was usually also high, 398 to 800 million. Mean egg densities often exceeded 10,000 eggs/1,000 m³ during June and July (Tables 18-20). The highest individual sample density, 147,000 eggs/1,000 m³, occurred during dusk to midnight, 1 July 1982. Densities over 90,000 eggs/1,000 m³ were recorded several other times during 1980-1982. No eggs were entrained during September, but a few (less than 1 million per month) were entrained during October and November.

Diel Abundance--

More fish eggs were entrained at night than during the day, notably during the midnight to dawn period, when 50-65% were entrained over each year, 1980-1982. During the dusk to midnight period, 15% to 44% of the eggs were entrained. The ANOVA showed there were significant differences in egg densities among diel periods during 1982 alone and 1975-1982 combined (p <0.001), but differences were not significant for 1980 (p = 0.374) or 1981 (p = 0.021) alone. The greatest mean densities of 1980 occurred 20-21 June and 14-15 July during midnight to dawn, 66,000 and 64,000 eggs/1,000 m³, respectively. Peak egg abundance for 1981 occurred on 13-14 July, when the midnight to dawn mean was 48,000 eggs/1,000 m³. The peak mean density for 1982 was 79,000 eggs/ 1,000 m³ during dusk to midnight, 10-11 June. A mean of 67,000 eggs/1,000 m³ occurred on 29 June-1 July 1982 (Tables 18-20). Patterns of diel abundance of fish eggs can be attributed to nocturnal spawning habits of alewife. Field-collected eggs increased in abundance from dusk to shortly after midnight; these were taken by plankton net throughout the water column. Alewives are pelagic spawners; their eggs sink, being slightly negatively buoyant. Thus alewife eggs would be entrained in the later part of the night. However, many eggs were entrained during the day, while few to none were ever collected in plankton nets towed during the day. Sled tows collect significantly more alewife eggs than do plankton net tows (Madenjian and Jude 1985). Divers often noted plumes of cold turbid water flowing along the bottom into the intakes on one side during certain times in summer, when the thermocline was far offshore (Dorr and Jude in press). We thus concluded that eggs that settled on the bottom were entering the intakes, increasing entrainment of these eggs over levels we would expect from plankton net densities.

Field-Collected Eggs

Seasonal Distribution --

Fish eggs were most abundant in field samples during June and July; they also occurred during April, May, August, and October 1980-1982 (Table 82). During early spring, eggs seldom occurred in open water. Both the number of samples containing eggs and densities of eggs increased sharply in June, usually decreasing somewhat in July and tapering off in August. No fish eggs were found in our samples during September or November 1980-1982, and only one October sample contained eggs. Peak sample densities (no./1,000 m³) recorded for each month were: April -476, May - 164, June - 70,160, July - 9,292, August - 1,212, and October - 66. Most of these peak densities were from beach samples during 1980 (Appendices 4-6). Results from 1980-1982 were similar to those observed in 1973-1979, with eggs occurring over a longer season in the beach zone than in open water (Bimber et al. 1984).

Diel Abundance--

Significantly more fish eggs were collected at night than during the day in the beach zone (Table 83). The vast majority of eggs taken in open water also occurred at night (Appendices 4-6). Since most fish eggs we collected were alewife eggs, alewife spawning habits explain the diel pattern of eggs: alewives are nocturnal spawners whose eggs are semi-demersal (Graham 1956; Mansueti and Hardy 1967). Thus alewife eggs could be collected by our gear at night, but most would have settled to the bottom by afternoon, when day sampling was conducted. Results for 1980-1982 are similar to our results from 1973-1979 (Bimber et al. 1984). During 1973-1979, egg abundance increased steadily from dusk to shortly after midnight, demonstrating increasing spawning activity. This pattern was also apparent in the 1980-1982 data.

Spatial Distribution--

Depth distribution-- Mean densities of fish eggs were usually higher in the beach zone than in open water during 1980-1982 (Table 82). This may be partly due to the demersal nature of the eggs, which would settle from the water column in open water, but could be resuspended in the beach zone and collected by our nets. Also, most spottail shiners spawn in the beach zone, thus more eggs may actually have been present. For 1974-1982, fish eggs were significantly more abundant at 6-m stations than at 9-m stations (Table 84).

Table 82. Mean densities (no. per 1,000 m³) of fish eggs collected at all beach and openwater stations near the D. C. Cook Plant, 1980-1982. Day and night sampling periods were combined.

Cook Plant versus Warren Dunes-- The ANOVA showed significantly more fish eggs were collected at Cook Plant open water stations than at Warren Dunes reference stations (Table 84). However, abundance differences were a function of the time when samples were collected. We generally followed the same sequence, and Warren Dunes stations were nearly always sampled earlier during the night. Whichever area was sampled later

generally had higher egg densities; sometimes no difference was apparent. In this respect, data from 1980-1982 showed the same trends as 1973-1979 (Bimber et al. 1984). June and July samples in 1980 and 1982 were collected first at Warren Dunes, then at the Cook Plant; egg densities were greater at Cook stations in those years. During 1981 June and July samples were collected first at the Cook Plant, then at Warren Dunes, and Warren Dunes egg densities were greater. Densities at beach station A (north Cook) were significantly greater than stations B (south Cook) or F (Warren Dunes); however, like open water data, these differences could not be attributed to the effect of the plant.

Vertical distribution—Distribution of fish eggs through the water column showed no consistent pattern. In 1980 and 1981, midwater densities were slightly higher than bottom densities, but in 1982, bottom plankton net tows collected more eggs (Appendices 4-6). Densities were highly variable, probably

because of patchy distribution of eggs due to spawning aggregations of fish. Bottom densities might be expected to be higher than upper strata densities due to demersal eggs. However, plankton net tows do not sample the lake bottom effectively and thus would miss the area of greatest egg abundance.

Field-Entrainment Comparison

Introduction--

We compared mean densities of fish eggs between field and entrainment samples. Field sample means were computed by taking means for each diel period (two) for stations C, D, and R (Cook) over all replicates (four at 6-m stations C and R, five at 9-m station D). Stations G and H (Warren Dunes) were omitted from the analysis because egg densities were usually much lower there than at the Cook Plant. Entrainment samples on the date nearest to field samples were used for comparisons (Table 85) to minimize changes in egg densities due to water mass exchange. The density computed for each diel division of entrainment sampling was the mean of four replicates. Density reported for each diel period (day or night) was the mean of two sets of samples (eight total), namely dusk-midnight and midnight-dawn for nighttime density and dawn-noon and noon-dusk for daytime density. Thus each diel comparison each month was based on 13 field and 8 entrainment samples. Exceptions were in June and August 1981 and July 1982, when the means of two entrainment sets (16 day samples, 16 night samples) were calculated because they were equidistant in time from field samples.

To compare annual trends in egg abundance between field and entrainment samples, we calculated mean density over the months May through August, using only entrainment densities on dates close to field sampling, as in the above comparison. We used Spearman rank correlation tests to compare abundance ranks of fish eggs in night field and entrainment samples. Rank correlation coefficients were computed by ranking mean densities each year, 1975-1982.

Seasonal Abundance--

Fish egg abundance patterns over the season were similar between entrainment and field samples, with the constraint that no field data were available during winter. Field and entrainment densities (1975-1982) were usually low in April and May, peaked in June or July, and decreased sharply through August, with a few eggs sometimes collected during the fall. However, mean densities did not always peak the same month for field and entrainment samples in a given year (Table 86; Bimber et al. 1984). In 1975, 1977, and 1982, field mean densities (day and night combined) were highest in July, and entrainment densities highest in June; in 1979 and 1980 entrainment egg means peaked in July while field densities peaked in June.

Table 85. Sampling dates used to compare field-caught and entrained eggs at the D. C. Cook Plant, May through August, 1980-1982. F = field, E = entrainment.

	Diel	1	980		1981	1	982

	night	12	11-12	12	10,13-14	10	18-19

Mean Density Comparison--

Mean densities of entrained fish eggs were nearly always greater than mean densities of field-collected eggs, 1975-1982 (Table 86; Bimber et al. 1984). Only in June 1979 was mean field density greater than mean entrainment density, and in that case field sampling occurred 6 days later than entrainment sampling. For both types of samples, night densities were nearly always greater than day densities, because of the nocturnal spawning habits of alewife, the main contributor to the eggs collected. Differences between field and entrainment densities were so marked, often orders of magnitude, that day entrainment densities frequently exceeded night field densities (Table 86; Appendices 1-6; Bimber et al. 1984).

Nighttime densities were used for comparisons between years. Mean densities of field-collected fish eggs were highest for 1979, followed by 1975 and 1980. Mean densities of entrained eggs were highest for 1978, followed by 1982 and 1980 (Table 86; Bimber et al. 1984). The Spearman rank correlation coefficient for field-collected vs. entrained egg densities ranked by year was 0.05, indicating no correlation.

Table 86. Mean monthly densities $(no./1,000 \text{ m}^3)$ of fish eggs in field (stations C, D, R) and entrainment samples at the D. C. Cook Plant, 1980-1982. Entr. = entrainment. N = number of samples included in mean.

The differences in magnitude and lack of yearly correlation between field and entrainment egg densities are probably primarily due to the demersal nature of fish eggs, coupled with

our sampling scheme. Plankton nets do not sample the bottom layer effectively, collecting only freshly released or resuspended eggs, thus biasing field densities downward (see Madenjian and Jude 1985). In contrast, the Cook Plant intake probably draws some cooling water from the bottom layer, where eggs collect. There are several items that provide evidence for this. Daytime sled tows on 18 June 1975 collected fish eggs at densities of 1,246, 6,839, and 21,399/1,000 m^3 at 18-, 15-, and 12-m stations respectively (unpublished data, Great Lakes Research Division, Univ. Mich., Ann Arbor, Mich. 48109), suggesting increasing egg densities with shallower water. Night sled tows had lower densities, probably because newly released eggs were still in midwater. Mean daytime density of entrained eggs was 1,885 eggs/1,000 m³ on 17-19 June 1975, less than sled tows would probably have collected at the intake depth. Mean daytime egg density from net tows at Cook stations, June 1975, was only $60/1,000 \text{ m}^3$ (Bimber et al. 1984). Daytime field egg densities from standard series sampling were very low in proportion to night field densities. Night:day ratios of mean densities for 1975-1982 combined were 157:1 for field-collected and 4:1 for entrained eggs. Thus, field data imply most eggs were spawned at night and sank to the bottom before day sampling, while entrainment data suggest eggs could be drawn from the bottom layer during daytime. Eggs from the lake bottom also probably elevated night entrainment densities over night field densities.

ESTIMATION OF ALEWIFE SURVIVAL DURING THE FIRST GROWTH SEASON

Introduction

Alewife larvae are widely distributed throughout inshore waters (1-9-m depth contours) of southeastern Lake Michigan, at all depth strata (Jude et al. 1979b). Juveniles (20-40 mm) inhabit the beach zone (1-3 m) during late summer, then begin offshore movement around September. Those hatched earliest move offshore first (Brown 1972). Supplemental trawling conducted offshore from the D. C. Cook Plant in 1978 showed few alewives occupied areas beyond the 15-m depth contour in October. Similarly, in eastern Lake Michigan near the J.H. Campbell Plant, juvenile alewives were most abundant at 1-1.5 m during September and 3-12 m during October, and alewife larvae were usually widespread over 1-15-m depths during summer (Jude et al. 1982). Therefore abundance of larvae and juveniles at 6 and 9 m (data used in this study) is considered to be representative of the inshore abundance of alewives.

Many young of the year (YOY) concentrate in bottom layers during fall (Wells 1968, Brown 1972). Midwater trawling and acoustical scanning done simultaneously with bottom trawls in eastern Lake Michigan showed that few alewives of any size were at midlevels in the water column (Wells 1983). In western Lake Michigan, echosounding indicated that more fish were in the water column at night than during the day; also, more alewives were collected in bottom trawls during the day than at night (Janssen and Brandt 1980). Although YOY alewives may ascend in the water column during turbulence (Wells 1968) and at night (our data), they were consistently more abundant in day trawls than at night near the D. C. Cook Plant. By expressing our trawl catch as number of YOY per 1,000 m3, these densities could be compared with densities of newly hatched larvae to yield survival estimates from hatching to the time of offshore movement during the first growth season. Hatch et al. (1981) and Argyle (1982) used similar methods to generate population estimates.

Results

During 2 years, 1977 and 1978, fish larvae densities in both field and entrainment collections were low and YOY densities high relative to other years (Table 87), resulting in improbably high survival rates (Table 88). During other years, using either entrainment or field fish larvae data, calculated survival from yolk-sac larvae to YOY was always below 2%. Mean densities of larval fish each year did not correlate well between field and entrainment samples, or between size groups within one type of

sample. The Spearman rank correlation among years for densities of 2-5 mm larvae between field and entrainment samples was 0.43. Rank correlations of densities for larger larvae between field and entrainment samples, and between size groups within one type of sample (field or entrainment), were all less than 0.7. The best correlation obtained (0.79) was between field and entrainment data for survival from yolk-sac larvae to YOY. Mean densities of 2-5-mm larvae over all years were similar between field and entrainment samples, 1,720 and 1,810 larvae/1,000 m³ respectively (Table 87), resulting in similar calculated survival rates over the entire study, about 1% from yolk-sac larvae to YOY (Table 88).

As expected, survival from postlarvae to YOY (averaging 2%) was nearly always greater than from yolk-sac larvae to YOY (averaging 1% - Table 88). Higher mean survival from postlarvae to YOY (10-33%) was calculated for larvae from separate length intervals 5.5-10 mm, 10.5-15 mm, 15.5-20 mm, and 20.5-25 mm using entrainment data (Table 88). When all lengths 5.5-25 mm of entrained larvae were pooled, calculated survival was 5% from postlarvae to YOY (Table 88).

Daily mortality rates generally declined over time (Table 89). When rates increased, which only occurred for design I, it was thought to be an artifact derived from long intervals between peak catches of two successive length groups (e.g., 18 days between 2-5 and 5.5-10 mm, compared with a 7-day estimation using Heinrich's data). Sampling at discrete times, a week or a month apart, sometimes allows actual abundance peaks to be missed and biases estimates.

Highest daily mortality (27.3%) was found for entrained larvae which passed from the 2-5-mm group to the 5.5-10 mm group (design II; Table 89). Lowest daily mortalities, around 2%, occurred for larvae and juveniles >15.5 mm. Length partitioning of entrained larvae demonstrated this rapid change in mortality over time; the change was not so evident when the wider length intervals were used.

Young of the year were less abundant at lengths of 15 to 34 mm than at greater sizes, although abundance did not peak at the same size in every year (Fig. 21). Alewives 15-34 mm were concentrated in shallower water than trawl depths; many in this size range were taken in beach seines, particularly during August. Modal size of alewives in trawls was usually between 35 and 64 mm. Alewives 35 to 64 mm probably have not reached overwintering size, since yearlings collected in April tended to be larger (mean size about 90 mm). Therefore, survival rates in this study do not reflect the entire growth season.

Discussion

Yearly mean densities and survival of alewife were not good predictors of year-class strength as measured by our data. Spring trawl catches of yearling alewife bore no relationship to larvae or young-of-the-year densities the previous year. Spearman rank correlations among years were all less than 0.5. Yearling alewives tend to inhabit midwater more than young-of-the-year do (Brown 1972), making bottom trawls unreliable estimators of yearling abundance and probably partly accounting for lack of correlation.

Adult alewives collected at Cook were not aged. Our catches in gill nets, trawls, and seines represented several age-groups, age 2 and older. Therefore, yearly densities and survival of first-year fish could not be related to yearly recruitment to the adult population.

Variation in yearly survival estimates may be due to either true survival differences or incorrect assumptions. Alewife survival is certainly not the same each year, as temperature, food availability, abundance of predators, and other conditions fluctuate irregularly and affect alewife survival. The high survivals calculated for 1977 and 1978 can be attributed to the

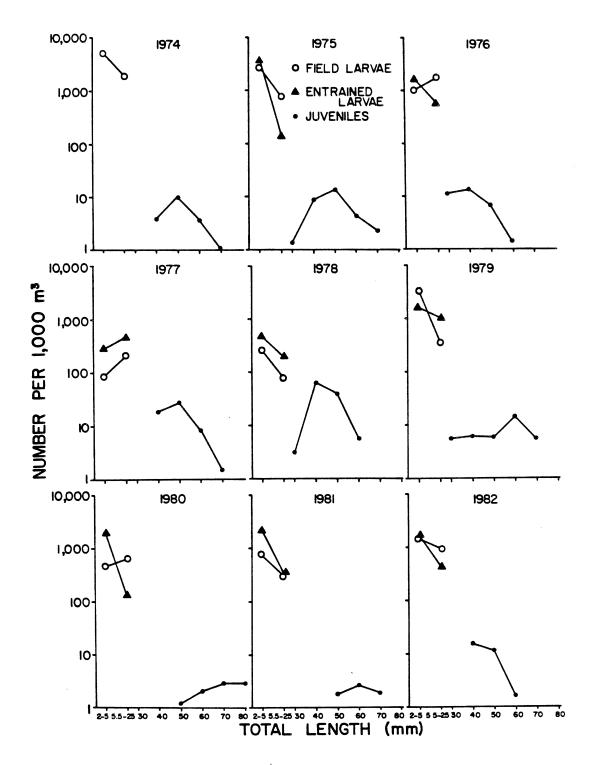

Figure 21. Catch curves for larval (2-5 mm and 5.5-25 mm) and young-of-the-year alewives collected near the D. C. Cook Plant, 1974-1982.

sampling schedule missing times of peak larvae abundance, or spawning and hatching taking place outside of the study area and juveniles moving into the area later (YOY collected by trawl). Either may occur fairly often, although weekly entrainment sampling is less likely to miss a hatching peak than is monthly field larvae sampling.

During a year of frequent and prolonged upwellings of cold water in eastern Lake Michigan, relatively few alewife larvae >5 mm were collected from 1-15-m depths, compared to larvae sampled during years of few upwellings (Heufelder et al. 1982). Upwellings may result in increased mortality to larvae or may displace larvae from the inshore zone (Heufelder et al. 1982). Thus differences in calculated survivals of post-yolk-sac larvae from year to year may be due to actual mortality differences or may be due to changes in distribution of older larvae from water mass movement. Yolk-sac larvae densities also may be depressed by direct mortality from upwellings or by transport through water mass movement. However, occurrence of newly hatched larvae was prolonged into September during a year of severe upwellings (Heufelder et al. 1982), possibly compensating for decreased densities (greater mortality or transport) by increased duration of occurrence (longer spawning season). Thus, yolk-sac larvae to YOY survival rates are apt to be less variable than post-yolk-sac larvae to YOY survival rates.

Other sources of variation which could influence survival rates include changes in trawling speed (thus distance trawled) and changes in trawl size, which can occur if trawling speed, currents or length of warp (line from boat to trawl) varies. Turbidity, illumination, and currents can affect net avoidance or escape of either larvae or YOY. Since trawl size was estimated, not measured, this was a possible source of error. Finally, the assumption that all YOY were near bottom may be wrong, but we have no concurrent midwater trawl data. Janssen and Brandt (1980) and Wells (1983) suggest that few alewives occupy midlevels during the day. If a significant proportion of the YOY were in midwater during the day, real survival rates would be higher than those reported here. Trawl size estimation may err in the opposite direction. Our trawl may not open as high as Hatch's, resulting in calculated YOY densities (and survival rates) being higher than actual values due to the trawl height factor in the adjustment of densities to the whole water column.

The "critical period" hypothesis, that the transition from yolk-sac larva to exogenous feeding is a time of high mortality (Hjort 1914, May 1974), is supported by our data. Survival from yolk-sac larva to post-yolk-sac larva is much lower than post-yolk-sac to YOY. The difference between entrainment and field data in post-yolk-sac to YOY survival may be due to entrainment sampling methods (pump or intake avoidance) or due to length-

interval partitions. If post-yolk-sac larvae are not separated into length intervals, this may result in artificially high densities because larvae of a given age may be vulnerable to sampling at successive sampling periods. If length intervals chosen are too small for sampling intervals, too low densities result (Farris 1960). Thus growth rates become a factor in the analysis, and post-yolk-sac larvae to YOY (age-specific) survival rates are more tentative than yolk-sac to YOY. Variations in growth rates over age, and between individual fish, result in apparent increases in survival and uncertainty as to correlation of age with length.

The daily mortality rates we calculated were comparable to those of other Clupeidae. Our daily mortalities from design II (Table 89) were similar to those found by Crecco et al. (1983) for American shad (Alosa sapidissima): 19.8-25.6% mortality per day for first-feeding American shad larvae, 4.3-8.7% for larvae approaching metamorphosis, and 1.8-2.0% for juveniles, while our alewife daily mortalities were 27.3%, 4.0-8.3%, and 2.0% for respective stages. Pacific herring (Clupea pallasii) larvae raised in enclosures showed a slightly different pattern (Schnack Although yolk absorption occurred at about 7 days after hatching, mortality was only 3-8%/day for the first 13-21 days, increasing to 20-30%/day for about a week following. Schnack attributed the increased mortality to starvation following yolk absorption. After 31-36 days from hatching, mortality decreased to 5-13%/day. Daily mortalities of round herring (Etrumeus teres), thread herring (Opisthonema oglinum), and scaled sardine (Harengula jaguana) for larvae 3-5 to 16-20 mm, were about 10%, 20%, and 22% respectively (Houde 1977a, 1977b, 1977c), higher than for alewife. Dragesund and Nakken (1971) found 94% mortality of Atlantic herring (Clupea harengus) during yolk absorption, between the 10- and 12-mm size groups. Pacific herring had 20-30% mortality per day over the first 20 days (Stevenson 1962). Survival curves for various herring differ regarding the presence and timing of a critical period (Dahlberg 1979).

We feel the truest representation of survival in this analysis is the ratio of density of yolk-sac larvae to density of YOY in the modal-length interval. Less abundant fish in certain length intervals of YOY represent fish that were more abundant at other depth contours than trawl depths, and density of older larvae is suspect due to growth rate uncertainty and variations in distribution.

APPENDICES

Appendix 1. Densities (no./1000 m³) for fish eggs and larvae entrained at the D.C. Cook Plant, southeastern Lake Michigan, 1980. Sample parameter codes are: Mpd (month period): consecutive number of the sample period during the annual sample program. Ser (series): (1) standard series, (2) supplemental sample, (3) problems-sample not used in calculations. Grt (grate): location of forebay grate, see Fig. 3 for reference. N/S (north/south): further designation of sampling location at each grate, (1) north, (2) south, (3) no designation, see Fig. 3 for reference. Dpt (depth): depth (m) of sampling in the forebay. Dl (diel): (N1) midnight to dawn, (D1) dawn to noon, (D2) noon to dusk, (N2) dusk to midnight, (LD and LN) long day or long night, samples extending beyond normal diel schedule, (0D and 0N) other day or other night, sampling was performed at irregular intervals. Temp: temperature (C) of intake water when the sample was collected. Refer to Table 12 for species designation. Blank entries indicate zero densities.

Date 12-08 12-08 12-08 12-09 12-09 12-09 12-09 12-09 12-09 12-09 12-09 12-17-18-18-18-18-18-18-18-18-18-18-18-18-18-	2 00	

Mpd (month period): consecutive number of the sample period during the annual Sample program. Ser (series): (1) standard series, (2) supplemental sample, (3) problems-sample not used in calculations. Grt (grate): location of forebay grate, see Fig. 3 for reference. N/S (north/south): further designation of sampling location at each grate, (1) north, (2) south, (3) no designation, see Fig. 3 for reference. Dpt (depth): depth (m) of sampling in the forebay. Dl (diel): (N1) midnight to dawn, (D1) dawn to noon, (D2) noon to dusk, (N2) dusk to midnight, (LD and LN) long day or long night, samples extending beyond normal diel schedule, (DD and DN) other day or other night, sampling was performed at irregular intervals. Temp: temperature (C) of intake water when the sample was collected. Refer to Table 12 for species designation. Blank entries indicate zero densities. Densities (no./1000 m³) for fish eggs and larvae entrained at the D.C. Cook Plant, southeastern Lake Michigan, 1981. Sample parameter codes are: sample program. Ser (series): (1) standard Appendix 2.

Appendix 3. Densities (no./1000 m³) for fish eggs and larvae entrained at the D.C. Cook Plant, southeastern Lake Michigan, 1982. Sample parameter codes are: Mpd (month period): consecutive number of the sample period during the annual sample program. Ser (series): (1) standard series, (2) supplemental sample, (3) problems-sample not used in calculations. Grt (grate): location of forebay grate, see Fig. 3 for reference. N/S (north/south): further designation of sampling location at each grate, (1) north, (3) no designation, see Fig. 3 for reference. Dpt (depth): depth (m) of sampling in the forebay. Dl (diel): (N1) midnight to dawn, (D1) dawn to noon, (D2) noon to dusk, (N2) dusk to midnight, (LD and LN) long day or long night, samples extending beyond normal diel schedule, (0D and 0N) other day or other night, sampling was performed at irregular intervals. Temp: temperature (C) of intake water when the sample was collected. Refer to Table 12 for species designation. Blank entries indicate zero densities.

Appendix 4. Densities (no./1000 m³) for fish eggs and larvae collected at beach (A, B, F) and open water (C, D, G, H, E, W, R) stations in Cook Plant study areas, southeastern Lake Michigan, 1980. See Fig. 1 for station locations. Date = month, day, year; Dl = diel period, D = day, N = night; Sta = station; Dpt = depth in meters, O = surface tow. See Table 12 for species corresponding to species codes.

Appendix 5. Densities (no./1000 m³) for fish eggs and larvae collected at beach (A, B, F) and open water (C, D, G, H, E, W, R) stations in Cook Plant study areas, southeastern Lake Michigan, 1981. See Fig. 1 for station locations. Date = month, day, year; D1 = diel period, D = day, N = night; Sta = station; Dpt = depth in meters, O = surface tow. See Table 12 for species corresponding to species codes.

Appendix 6. Densities (no./1000 m³) for fish eggs and larvae collected at beach (A, B, F) and open water (C, D, G, H, E, W, R) stations in Cook Plant study areas, southeastern Lake Michigan, 1982. See Fig. 1 for station locations. Date = month, day, year; D1 = diel period, D = day, N = night; Sta = station; Dpt = depth in meters, O = surface tow. See Table 12 for species corresponding to species codes.
